Predators, Parasites and Diseases Spotted Hyenas *Crocuta crocuta* and Lions *Panthera leo* are potential predators, particularly of foals and yearlings. There are no known data on parasites and disease, although *Strongyle* spp. have been recorded in faecal samples collected in the Danakil Desert.

Conservation IUCN Category: Critically Endangered C2a(i). CITES: Appendix I.

The major threat to the African Wild Ass is hunting for food and medicinal purposes, particularly in Ethiopia and Somalia. According to local pastoralists in these areas, body parts and soup made from bones are used for treating tuberculosis, constipation, rheumatism, backache and boneache. The soup is also fed to their livestock to alleviate mineral deficiencies (Moehlman *et al.* 1998). In Eritrea, the Afar pastoralists do not shoot wildlife and guns are strictly controlled. If African Wild Asses were to be adequately protected, then the major remaining threat would be access to water and sufficient forage. Reproductive ♀♀ and their less than three-month old foals are most at risk. Hence, it will continue to be important to determine critical water supplies and basic forage requirements, thus allowing management authorities

to determine (in consultation with local pastoralists) how to conserve the African Wild Ass. In Eritrea, Ethiopia and Somalia, all elders that have been consulted have expressed concern that the African Wild Ass be protected and conserved. A third major threat to the survival of the African Wild Ass is possible interbreeding with the domestic donkey.

In Ethiopia, Yangudi-Rassa N. P. (4731 km²) and Mille-Serdo Wild Ass Reserve (8766 km²) were established in 1969. However, the former has never been formally gazetted, and both areas are utilized by large numbers of pastoralists and their livestock. These areas are remote and extremely arid, and the Ethiopian Wildlife Conservation Organization (EWCO) has not had sufficient funds or personnel for appropriate management (Kebede 1999). In Eritrea, the government designated the African Wild Ass area between the Buri Peninsula and the Dalool Depression as a high-priority area for conservation protection as a nature reserve. There are no protected areas in the range of the species in Somalia.

Populations of Somali Wild Ass are maintained in captivity.

Subgenus *Hippotigris* Zebras

Hippotigris Hamilton Smith, 1841. Jardine's Naturalist's Library, Mamm. 12: 321, pl. 21–25.

The subgenus *Hippotigris* is currently taken to embrace all zebras, the main distinction of which is being wholly or partially striped. The taxonomic name implies a common striped ancestor and an assumption that the various zebra species represent variations derived from that inheritance (whether inclusive of *Equus* and *Asinus* or not; Bard 1977). If all equines had striped ancestors, all the subgenera become redundant (Darwin 1859, Orlando *et al.* 2009).

Striping, whether complete or partial, poses questions of great biological importance so this profile is primarily a discussion as to the possible origins of a visual pattern that is uniquely extreme among mammals, yet is shared to some degree by zebra duikers, zebra finches, zebra fishes and even zebroid insects. The fact that areas of strongly contrasting black and white patterning are found across such a wide range of organisms and presumed functions, reveals that this common, highly conspicuous, visual phenomenon can serve many needs at many different scales. Any universal function for black and white stripes must lie in the peculiar behavioural history of each striped organism and how that behaviour has enlisted optical neurophysiology

in the service of that behaviour. The unstriped relatives of striped animals provide clues to the meaning of striping, and in relation to zebras and horses there are two crucial questions. The first is whether striping is an eccentric embellishment, possibly a convergent one, in a few outlying, even marginal species. The second asks whether striping represents a primary and biologically significant adaptation among an entire lineage of animals, in this case living equids.

Historically, horses and asses were the animal models with which scientifically minded cultures were first familiar; zebras only became an exotic curiosity much later. Even today, zebras remain aberrant animals in minds and vocabularies, engendering a popular folklore that has inhibited serious scientific investigation of an important phenomenon. This legacy is evident in numerous attempts (most of them casual, some even cavalier) to link striping with supposed or real environmental oddities of Africa (Ruxton 2002). Striping, across many taxa of vertebrates and invertebrates, has evolved to be registered in the eyes of whatever animal is most likely to be a beholder; furthermore, for most striped fauna, 'beholders' (or visual signal receptors) are much

Polymorphism in three equine populations. First column, *Equus quagga boehmi*; second column *Equus quagga quagga* (from skins, photos and contemporary paintings); third column *Equus ferus*, from palaeolithic rock paintings in Dordogne (courtesy of Natural History Museum library, London).

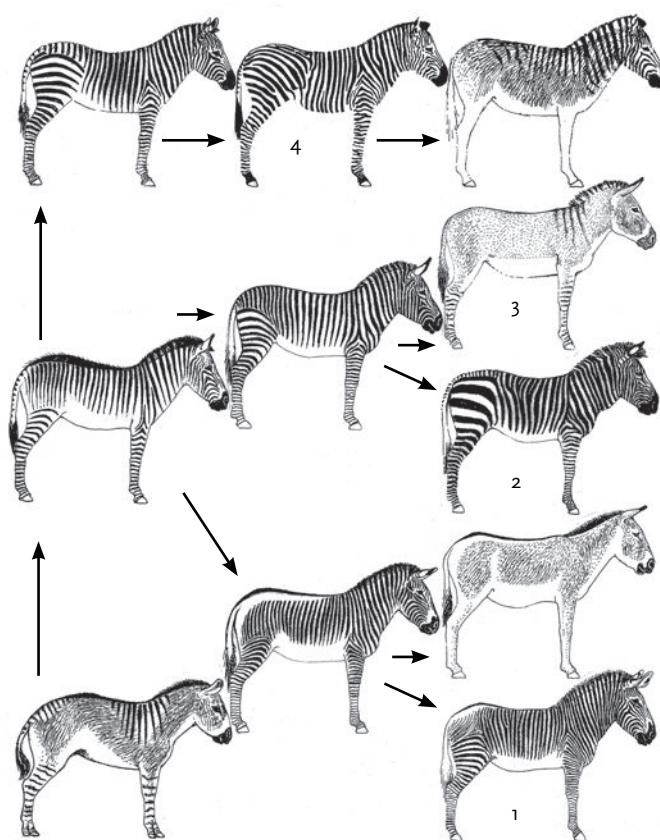

less likely to be predators, competitors or parasites (e.g. Waage 1981) than conspecifics. Thus intra-specific behaviour and the susceptibilities of eyes are the most promising starting points for any enquiry into the primary role of stripes in animals (Gibson 1966).

Several horse, ass and zebra studies have tended to seek out and emphasize differences between species, especially in relationships between ♂♂ and ♀♀ (e.g. Klingel 1967, 1972, Joubert 1972a, Tyler 1972). In spite of such differences within their social systems, zebras actually share some significant behavioural, ecological and biogeographic characteristics that differentiate them from horses and asses. In their wild form, horses were polymorphic animals living at variable densities, and adapted to very cold seasonal temperate climates in the northern continents, while monomorphic asses were mainly desert and near-desert animals living at low densities. Zebras, by contrast, often live at very high densities and originally occupied a very broad spectrum of less extreme, tropical and sub-tropical grassy environments, most of them subject to much seasonal or periodic fluctuation in climate and resources. In terms of ecological zoning, horses and asses occupied the least benign zones, while zebras formerly dominated the prime habitats. In this respect a striking peculiarity of all zebras, and one that is clearly adaptive for fluctuating resources and unpredictable densities, is the ease with which they move, congregate or disperse, often within the space of a single day.

Zebras are famously 'social' in that they can join up with hundreds of other zebras or jostle with herd antelopes at a water source or pasture and then break up into much smaller units. In contrast with other herbivores, notably antelopes (which expend much energy and time in elaborate socio-sexual behaviour), social ties between individual adult zebras are generally remarkably loose and fluid. Time spent on social interaction is more expensive for non-ruminant zebras, which have to cover much more ground and spend about twice as much time grazing as their ruminant equivalents because they have to pass more grass, at a faster rate, through their digestive tract. Adult zebras seem able to bypass elaborate social behaviour and abbreviate their interactions with other zebras and this exceptionally easy coming and going is facilitated by the adults of both sexes lacking any lasting attachments, particularly to members of their own sex. Yet male zebras fight fiercely over oestrous ♀♀ (Klingel 1968a, Joubert 1972a) and latent intolerance is also implicit in diminished or rudimentary attachments among adult ♀♀. By contrast, female zebras and their most recent offspring (and young zebras of similar age) have intense attachments that are most obviously expressed in much mutual nibbling.

A young zebra, growing up beside its mother, and with other neighbouring zebras, is no different from horses, asses, or any other social young animal in associating its mother with milk and its fellows with the security of living within a group, but it differs very strongly in its visual environment. From birth onwards, it is, like any other mammal, 'learning to see', but what it sees within a zebra herd is fundamentally different. In the early stages of visual learning, orientation-selecting neurons are particularly important, and black and white stripes (particularly vertical ones, which are efficient signallers of horizontal movement) are known to activate a set of early-stage, direction and orientation-selective neurons and few other visual stimuli are able to trigger such strong responses (A. Hurlbert pers. comm.).

The presence of stripes introduces an exceptionally assertive type of visual stimulation into the young animal's world and this difference from other, un-striped animals is emphatically not trivial (Kingdon

Stripe patterns on five extant equids and hypothetical ancestral patterns (numbers indicate the likely sequence of ancestral arrival/evolution in Africa): *bottom left*, beginnings of common ancestral pattern; *middle left*, common ancestor of all surviving *Equus* species; *top left*, ancestral pattern for Plains Zebra *Equus quagga*; *top middle and top right*, *Equus quagga* ssp.; *middle centre* common ancestor of African Wild Ass *Equus africanus* and Mountain Zebra *Equus zebra* (to right); *middle bottom*, common ancestor of Kiang *Equus kiang* and Grévy's Zebra *Equus grevyi* (to right).

1984). Anyone who has watched zebras attentively will have become aware that eyes have to work overtime to accommodate to their every movement. Each time an animal changes the angle of its body the eye registers the vertical stripes *actually* getting wider or narrower (depending on how close to broadside it is) while horizontal stripes, instead, keep a similar width. Research has shown that individual visual nerve cells in mammals are programmed to respond to certain primary properties of the seen environment and different cells register different properties (Blakemore 1971). Thus, the process of seeing is essentially modular and is mediated by large batteries of specialized visual receptors (Gibson 1966, Mollon 1974, Zeki 1993). Research has also shown that black and white stripes can trigger an identifiable selection of these specialized visual neurones, notably those that register: (a) brightness contrast; (b) colour contrast; (c) edge contrast; (d) edge orientation; (e) spatial frequency; (f) direction of motion; and (g) temporal flicker (Zeki 1993). In real life it is likely that this battery of receptors play their narrow roles as part of the machinery of seeing, helping eyes and brains to extrapolate such useful information as directional movements and distance and thus contribute to making sense of the total environment. Because zebra stripes are unambiguously a visual phenomenon it becomes important to recognize that the complicated processes of seeing, and responding to what is seen, enlist just such a range of separate,

specialized receptors. Somehow, zebras have evolved a pattern that isolates such visual responses from their normal environmental contexts. Black and white stripes represent a sort of abstraction of what eyes are hungry to see!

Strong physiological responses can be stimulated in mammalian eyes by patterns that successfully isolate the particulate, component-specific properties of cells within the visual cortex. Stripes, particularly vertical stripes, trigger responses in early-stage, motion-selective neurons, which are functionally tuned to register the direction of motion (A. Hurlbert pers. comm.). It is this specialization of visual neurons that is central to the proposal that the overall striping of zebras has evolved in *direct* response to the *separate* sensibilities of these neurons. Also central to this concept is the detachment of striping from individuality, manifest in the observable conditioning, of young zebras, to respond indiscriminately, and with every sign of being 'attracted' to stripes, regardless of their 'owner'. As it matures, the young zebra seems to find almost any fellow zebra attractive and they can even be drawn towards zebras of another species (behaviour that is particularly frequent among Plains Zebras *Equus quagga* and Grévy's Zebras *E. grevyi* in Laikipia in Kenya). More important, especially for its general application to the evolution of visual signals of all sorts, the suggestion here is that visual signals are effectively 'designed' in the eyes of their beholders – in this case, the eyes of other zebras.

Central to understanding the evolution of stripes is relating their beginnings to their function in the behavioural repertoire. There may have been some shifts over time but some continuity must be expected. Stripes could, of course, have derived from the alteration of some pre-existent pattern with stripes aligning themselves out of, say, a scatter of cryptic spots and squiggles, such as are common on many juvenile mammals and birds that need to hide from predators. Additionally, or alternatively, striping in zebras could have begun with exaggeration of some detail of surface morphology that was significant in the behavioural repertoire of the zebras' common ancestor. A scan of the behaviour of contemporary zebras offers hints as to what that detail might have been and suggests an explicitly social function for stripes. The clue comes from one of the few easily observed signs of 'friendliness' among zebras (Kingdon 1979, Cloudsley-Thompson 1984).

Skin-nibbling is integrated into the single most important affiliation in zebra society, namely the mother–young bond. Directly and indirectly, that bond is likely to provide the social glue that holds zebra societies together. Furthermore, zebras do not nibble at random; they approach, nose to nose and prefer the point where the neck meets the shoulder above all other sites, although the root of the tail and lower rump are also popular. Of course, mothers, partly because they are so much taller, have little choice but to nibble the base of their offsprings' manes and backs (which in itself might have established a very early taste for being nibbled on the shoulder and explain its universality among equids). Young foals, instead, cannot reach their mothers' shoulders and must be content with her legs, flanks and face, but the preference for nibbling shoulders is evident in the interactions of similar-aged foals.

In adopting mutual skin-nibbling as a bonding device zebras resemble some primates and many other social mammals that have appropriately shaped incisors in both jaws. The fact that tactile grooming is such a basic feature of social relations, especially for ♀♀ and their young, yet declines as the animal matures is an anomaly

that has evolutionary implications that, in turn, raise larger questions about the underlying mechanisms that have shaped zebra society. Because body-grooming with the incisor teeth is such a widespread bonding behaviour among many different orders of mammals, assuming similar habits in early equid ancestors is not unreasonable.

The most striking feature of the neck–shoulder junction is that the skin has to be fairly loose there to accommodate to a lot of neck movement. This looseness gives rise to vertical folds or skin wrinkles, which would be unremarkable were it not for the fact that many organisms respond to, or need, just such visual markers to help direct their species-specific behaviour. When such attention-attracting foci become 'target areas' it is not uncommon for them to be visually advertised. Therefore, ancestral equids would have been conforming with a very widespread phenomenon had they evolved light and dark vertical streaks to exaggerate and advertise the vertical skin folds on their shoulders. Knowing that all equids still target the shoulder for grooming and that the majority of species (always or sometimes) have striped shoulders makes it plausible that this preferred 'target area' was the starting point for stripes. Projecting that connection back into evolutionary time to suggest that stripes spread out and away from the shoulders, making the entire animal one huge, three dimensional 'target area' (which living zebras, indeed, *are*), is completely consistent with the functional behaviour of living zebras.

Early equids were relatively small and probably lived permanently on small, exclusive territories as vulnerable browsers, but there was a general trend toward larger body sizes. While some conservative types probably continued in closed habitats the lineage that led to modern equines became mobile grass eaters living in much more open grasslands and savannas, a change evidenced by a progressive elongation and deepening of fossil skulls, ever more hypsodont teeth and progressive elongation and simplification of the limbs (Simpson 1951, Radinsky 1969). A major correlate of this shift into more open habitats would have been greater sociality, a behavioural change that must have been inhibited and complicated by many millions of years of largely solitary existence.

The evolutionary conversion of previously solitary or territorial species into ones that are able to live in large, aggregated groups is generally recognized as being problematic and some of this literature is summarized in the profiles of social carnivores and rodents such as

Preferred head/rump positions in Grévy's Zebra *Equus grevyi* ('empty chewing' by partner on left).

mole-rats. In zebras the fact that young animals are more tactile than adults and some suggestive changes in their behaviour as they mature hint at an extraordinary transformation in social behaviour. The one-on-one tactile bonding of mother and foal, or colt with filly, changes into a more superficial but socially very effective type of visual bonding in which *any* zebra becomes attractive. The sequences of this transformation can be observed in the behaviour of free-living zebras as well as extrapolated from other sources. These have been detailed in Kingdon (1979) but can be summarized as follows.

The browsing ancestors of zebras were unlikely to have had any more than discrete, striped 'target areas' on their shoulders, but the proposed, unique optico-neurological effects of stripes, as described earlier, might, even then, have had a unique 'conditioning' effect on the physiology of nibbling partners. This effect was to associate neuro-physiological sensation (induced by stripes that dominated the visual field of the nibbler) with social interactions that can look quite 'trance-like' to a human observer. The transition from actual nibble-grooming to non-tactile partner-seeking can be observed in the behaviour of maturing Plains Zebras. Nibbling involves small nodding movements of the head (remember that movement, in viewer or viewed, intensifies the physiological impact of stripes) and young zebras can be seen nodding and champing, sometimes centimetres away from their partner, sometimes a metre or more. 'Empty chewing' and head nodding are the clearest indications that a switch in sensory channels is taking place: from tactile to visual. It is at this stage that the young zebra begins to find any other zebra attractive.

A small panel of stripes may have first induced a close-up visual reward, but the social benefits of finding another equine 'attractive' would have exerted real selective pressure for the striped area to expand, thus enlarging the distance at which their physiological sensations could take effect. The progressive evolution of stripes and their refinement would have been based on a preference for heightened contrast and well-defined edges and spacing, in the eye or visual cortex of the viewing zebra. This preference can be predicated on the fact that stripes are powerful visual signals and that any movement is automatically stimulating for the eye. Even when no more than a single stripe is visible in close-up, a single sharp edge should still be sufficient to trigger a strong response in the (nibbling) viewer; a panel of multiple stripes amplifies the effect.

Optimal distances between zebras are a topic in their own right and it is sufficient here to note that there is some evidence that zebra species differ in their preferred inter-zebra spacing: Grévy's Zebras prefer to stand closer than 2 m, while Plains Zebras tend to stand more than 2 m apart (Kingdon 1979, Cloudsley-Thompson 1984). If the spacing of stripe patterns correlates with species-specific behaviour and species prefer particular frequencies or conformations then optimal spacing of individuals may well have a visual component.

The ontogenetic sequences that can be observed in living zebras parallel and approximate to a sequence of evolutionary changes. These effectively allow zebras to convert a one-on-one tactile bond into a multiple-partner visual bonding system. This interpretation helps explain how zebra stripes have evolved to promote the very peculiar social flexibility that is characteristic of zebra societies. Striping may have been a key adaptation for many more ancestral equines than those currently treated as 'tiger-horses' *Hippotragus*.

Equus grevyi GRÉVY'S ZEBRA

Fr. Zèbre de grévy; Ger. Grevy-zebra

Equus grevyi Oustalet, 1882. La Nature, Paris 10 (2): 12. Described as 'region de l'Afrique orientale qu'on appelle le pays des Gallas', restricted to Awash Valley by Yalden *et al.* (1986).

Grévy's Zebra *Equus grevyi*.

Taxonomy Sometimes included in the subgenus *Dolichohippus* (see Groves 2002). Pocock (1902) described a subspecies of Grévy's Zebra (*berberensis*) that has sometimes been regarded as distinct, although the feature on which it was described (brown rather than black stripes) is an age-related feature (Groves & Bell 2004). Groves (2002) provisionally listed two subspecies of Grévy's Zebra: *Equus grevyi grevyi*, from the northern part of the range, and an unnamed subspecies in the south (with localities in Meru, Ewaso Ng'iro and Lngayo Water). However, Groves & Bell (2004), analysing a small sample of Grévy's Zebra skulls, concluded that the species is indeed monotypic. Synonyms: *berberensis*, *faurei*. Chromosome number: $2n = 46$, with 32 metacentric and 12 acrocentric; both X and Y are metacentric or submetacentric (Benirschke & Malouf 1977, Ryder *et al.* 1978). Cordingley *et al.* (2009) report evidence of natural hybridization between Grévy's Zebra and Plains Zebra *Equus quagga* in Laikipia in C Kenya. All first-generation hybrids were the offspring of Plains Zebra ♀♀ and Grévy's Zebra ♂♂. Two hybrids successfully raised foals to over 3 months of age, including one that reached adulthood, indicating the fertility of female hybrids and viability of their offspring.

Description The largest extant wild equid. Long-legged and long-faced, with characteristic large, ovoid ears. Muzzle brown with white margin before fine black and white stripes. Neck broad with thickest stripes on body. Mane thick and upright, black and white although tips appear black. Body uniformly striped with a chevron at shoulder and haunch. Flank stripes fine and vertical, tapering out at a level above elbow, leaving belly white. Dorsal and ventral black stripes present. Dorsal stripe broad and prominent, particularly over rump where a white margin increases in breadth. Leg stripes dense and merge at fetlock. Stripes on hindquarters curl down from dorsal stripe around hindquarters and taper out leaving buttocks white. Dorsal stripe continues on tail. Sexual dimorphism slight, with ♂♂ weighing 10% more than ♀♀ (King 1965). Males and ♀♀ easily distinguished (notably more so than Plains Zebra) by conspicuous black labia of ♀♀. Foals' stripes brown and less defined than those of adults. Foals' stripes turn black and become more defined as they age, starting with neck and ears, followed by head and limbs, and finally ending with flanks. Dorsal stripe remains brown-black and fluffy for up to two years. One pair of nipples.

Lateral, palatal and dorsal views of skull of Grévy's Zebra *Equus grevyi*.

Groves (2002) mentions a number of characteristic cranial features, including: a very elongated skull, exceeding the cervical spine in length (unlike other subgenera); occiput high and raised; postorbital constriction deep; muzzle and vomer long; and nasal end of the premaxilla rounded and wedged into the nasal. Males have large upper and lower canines, absent in ♀♀.

Geographic Variation See Taxonomy.

Similar Species

Equus quagga. Only species that may be confused because of range overlap in N Kenya. Relatively smaller; head shorter; ears small and pointed; muzzle black; stripes broad, particularly over flanks and hindquarters; hindquarter stripes curl up from ventral stripe back across hindquarters towards buttocks.

Distribution Confined to arid and semi-arid areas of the Horn of Africa, specifically Ethiopia and Kenya.

Historical Distribution Historically, Grévy's Zebra ranged east of the Rift Valley in Kenya (Stigand 1913, Stewart & Stewart 1963) to W Somalia, and from Alledeghi Plain, through the Awash Valley, the Ogaden, and north-east of L. Turkana in Ethiopia to north of Mt Kenya and south-east down the Tana R. in Kenya. There are no confirmed records from Eritrea (Yalden *et al.* 1986, Bauer *et al.* 1994), nor from Djibouti (though mentioned by Simoneau 1974) or adjacent Somaliland.

Current Distribution Today, Grévy's Zebra has a highly discontinuous range, being found from the eastern side of the Rift Valley in Kenya to the Tana R. There is a small, isolated population east of the Alledeghi Plains north-east of Awash N. P. in Ethiopia. From L. Ch'ew Bahir in S Ethiopia, the population is not contiguous, but extends to just north of Mt Kenya although a few animals are found further south-east along the Tana R. There is a small population in and around Tsavo East N. P. in Kenya that was introduced in the 1970s. They are considered to be extirpated from Somalia (where the last confirmed sightings date to 1973); sightings from S Sudan require confirmation (Williams 2002). Over the past four decades, Grévy's Zebras have

Equus grevyi

Variations in the width of stripes in Grévy's Zebra *Equus grevyi*.

expanded their range onto the Laikipia Plateau, primarily for anthropogenic reasons.

Habitat Grévy's Zebras live in arid and semi-arid (annual rainfall range 100–650 mm) grass/shrubland where there is permanent water (Klingel 1974, Rubenstein 1986, Rowen & Ginsberg 1992, Williams 2002). The lack of free-standing water ultimately limits their incursion into more arid areas to the east and north, while competition with other grazers, including Plains Zebras, may limit their distribution into more mesic areas (Bauer *et al.* 1994). Yalden *et al.* (1996) recorded them to 1600 m in Ethiopia. Human presence, including corrals and small hamlets, also limit the area available for Grévy's Zebras, affecting both their use of water and rangelands (Williams 1998, Sundaresan *et al.* 2008).

Two examples of bispecific association among zebras: (a) having clumped after a scare, a grazing 'fan' forms in Grévy's Zebra *Equus grevyi*; (b) grazing association, note tendency to form parallel pairs in both spp.

Abundance Grévy's Zebras have undergone significant declines in numbers. In Kenya, a 70% decline in the population took place between 1977 and 1988 (13,700 to 4276 animals, respectively; Rowen & Ginsberg 1992, and references therein). A subsequent survey of N Kenya in 2000 indicated that the number of animals declined to between 2500 and 3000 (Williams 2000); this estimate was later revised to between 1600 and 2000 animals surviving in Kenya (Williams & Low 2004). The largest subpopulation, estimated to harbour over 90% of the global population, is found at the southern end of their range in Kenya; this subpopulation ranges from Lewa to Samburu N. R. from south to north, and from Garba Tula to the Laikipia plateau from east to west. A recent aerial survey of this Laikipia–Samburu subpopulation resulted in an estimate of 2400 animals (Litoroh *et al.* 2010).

A population decline of a similar order of magnitude was also recorded in Ethiopia: the population was estimated at approximately 1500 in 1980 (Klingel 1980, Rowen & Ginsberg 1992), while aerial surveys in 1995 suggested a total of only 500–600 animals (Thouless 1995a, b). Recent counts put the population at perhaps no more than 120 individuals, indicative of a 93% decline in numbers in Ethiopia since 1980 (Williams *et al.* 2003).

In total, then, it is estimated that there are no more than 2700 Grévy's Zebras remaining in the wild.

The density of animals fluctuates seasonally as animals move in their search for resources. During the wet season, the zebras are widely dispersed. During the dry season, when they are dependent on permanent water, they are more concentrated. However, given that they can move up to 35 km from water even during the dry season, their densities are never high. They are most abundant and most easily observed in the southern end of their range in Kenya, where they reach 2.4 animals/km² (S. D. Williams pers. obs.).

Adaptations The physiological adaptations to living in hot arid and semi-arid areas are largely unknown, partly due to lack of detailed research. However, it has been recorded that mares without foals only need to drink every five days (Becker & Ginsberg 1990). In addition, they display behavioural characteristics that may facilitate their survival in such an environment. They will rest – in the shade if it is available – during hot, midday periods. During the dry season, as water availability declines, they have been observed to dig in dry river beds to access water (Klingel 1974, S. D. Williams pers. obs.). Finally, the facultative ability of ♀♀ and bachelor ♂♂ to be highly mobile has been interpreted as an adaptation to the unpredictability of their environment (Williams 1998).

It is thought that foals are energetically constrained (see Reproduction and Population Structure; Rubenstein 1989, Williams 1998) and foals

Characteristic ovoid ears and broad neck stripes (left) and rump 'target' design (right) of Grévy's Zebra *Equus grevyi*.

will not travel to water with their mothers but remain in 'kindergartens' up to 8 km from water (Klingel 1974, Rubenstein 1989, Becker & Ginsberg 1990, Rowen 1992, Williams 1998). While in a kindergarten, foals are vulnerable to predation. Foals display no specific anti-predator behaviour (Klingel 1974), although an adult may sometimes remain with them.

Foraging and Food Grévy's Zebras are predominantly grazers, with preferred grass species including *Cynodon dactylon*, *Pennisetum mezianum*, *Aristida adscensionis*, *Chloris virgata* and *Chrysopogon plumulosus*. In stressed conditions, such as during times of drought, browse (e.g. *Sericocomopsis* spp., *Salsola* spp., *Disperma* spp.) can comprise as much as 30% of their diet (Rowen & Ginsberg 1992). Like other equids, Grévy's Zebras make decisions about where to feed and the time spent feeding (43–62% of the time depending on reproductive condition; Ginsberg 1988) to maximize their intake rates. During the dry season or in overgrazed areas, they feed in swards with the highest biomass (Ginsberg 1988, Williams 1998). These swards are often patches with high fibre grasses (e.g. *Pennisetum* spp.) that are not tolerated by domestic livestock. The level of fibre may become intolerable to the zebras, at which point they disperse, often over large distances, in search of other pastures (Ginsberg 1988, Williams 1998). Consequently, with food availability becoming less predictable with overgrazing of areas by domestic livestock in recent times, Grévy's Zebras were recorded in recent studies to be moving during the dry seasons as they were recorded to do only in droughts in earlier studies (Ginsberg 1988, Williams 1998).

In more mesic areas into which Grévy's Zebras have recently expanded their range, different reproductive classes were recorded to make different habitat selections with bachelor ♂♂ and lactating ♀♀ choosing shorter, greener swards than other reproductive classes (Sundaresan *et al.* 2008).

Free-standing water is a requirement of their diet. In much of their range, this is in the form of springs. In the absence of pastoral people (thus, in protected areas), Grévy's Zebras drink in a four-hour time window at the middle of the day, probably to reduce the risk of predation at water sources. In areas used by pastoral people, they are excluded from the use of water during the day and drinking shifts to night-time (Williams 1998).

Social and Reproductive Behaviour Grévy's Zebras are social animals. They form two types of association, depending on reproductive condition and resource availability. Females with young foals are typically predictable in their patterns of association, forming relatively stable groups with other ♀♀ with whom they are in reproductive synchrony (Ginsberg 1989, Becker & Ginsberg 1990, Rowen 1992, Sundaresan *et al.* 2007b). They also may associate more strongly with one ♂ to reduce male harassment (Sundaresan *et al.* 2007a). Females without young foals (and ♀♀ with foals in overgrazed areas) are relatively less predictable (although more so than some other species of equid – e.g. Onagers *Equus hemionus onager*; Sundaresan *et al.* 2007b). Their associations are fluid since their movements are determined by the availability of resources. Group composition can, therefore, be unstable and can change on a daily basis (Klingel 1974, Ginsberg 1989), implying that decisions of habitat use and association are being made at the level of the individual. Group size is variable (range 1–>150 animals). Territorial ♂♂ are often solitary although they will associate with conspecifics and other animals (including those of other ungulate species such as Beisa Oryx *Oryx beisa*, Giraffe *Giraffa camelopardalis* and Plains Zebra).

Recorded home-range size of non-territorial individuals is up to 10,000 km² (Ginsberg 1988, Rowen & Ginsberg 1992, Williams 1998). They are extremely mobile and individuals have been recorded to move distances of greater than 80 km, sometimes returning to the original area within weeks (Williams 1998). Their movements are determined by resource availability. During the wet season, when not constrained by available water, they disperse. As the dry season progresses, their ranges contract around water sources. During droughts they can disperse huge distances in search of food and water (Ginsberg 1989, Williams 1998). During dispersal episodes resulting from depleted food, different reproductive classes have different thresholds. Females without young foals disperse first as they are not constrained to remain in the vicinity of water. If food resources continue to decline, mares with young foals also disperse often leaving only territorial ♂♂ (Williams 1998). Territorial ♂♂ will disperse only in extreme conditions when resources dictate and will be the first individuals back into an area following the onset of the wet season (Klingel 1974, Ginsberg 1988, Williams 1998).

Breeding ♂♂ defend resource territories (water and food being the key resources) of 2–12 km² distributed in a mosaic across the landscape. The formation of territories may have evolved in response to the distribution of ♀♀, although the possession of a territory is not a guarantee for reproductive success, and thus ♀♀ do not visit all areas of the territory mosaic (Klingel 1974, Ginsberg 1989). They have a high degree of territorial fidelity and may hold territories for up to seven years (Ginsberg 1988). Territorial ♂♂ are generally larger than other ♂♂ (Ginsberg 1989). They mark their territories with dung piles that are not necessarily placed on the periphery of territories but are often found on paths that are frequently used by

other zebra (for example, those to and from water sources; Ginsberg 1988). Territorial ♂♂ also advertise their tenure of a territory using a characteristic vocalization that could be described as a very loud bray followed by a strangled squeak. They also advertise using a distinctive upright posture. The territorial ♂♂ tolerate the presence of bachelor ♂♂ but will chase them in a ritualized manner when an oestrous ♀ is present (Klingel 1974, Ginsberg 1988). Fighting between ♂♂ is uncommon although bachelor and territorial ♂♂ will often spar to establish a dominance hierarchy (Ginsberg 1988).

In contrast to the ♂♂, the reproductive condition of the ♀ determines her resource requirements and thus distribution relative to resources. Thus, when the distribution of grazing allows it, lactating ♀♀ are found predictably closer to water than other classes of ♀♀ and they typically associate with and mate with one ♂ whose territory has access to water (Ginsberg 1989, Rowen 1992, Williams 1998). However, in large parts of their range, where forage is sparse (or where the first 6–7 km from water has been altered by overgrazing by domestic livestock), lactating ♀♀ must move large distances (up to 13 km; S. D. Williams pers. obs.) to and from water to reach adequate grazing (Williams 1998). This means that they move through a number of territories, which, in turn, means that they may mate with many ♂♂. Non-lactating, cycling ♀♀ are similarly typically promiscuous, moving through numerous territories in search of adequate resources and, therefore, mating with many ♂♂.

Male behaviour is dependent on female behaviour (and, therefore, reproductive condition) and they will display mate-guarding with promiscuous ♀♀. During courting, a territorial ♂ will repeatedly mount the ♀ in oestrus, with neither an erect penis nor intromission, while braying and squealing loudly. When intromission does occur, copulation is always silent. Following copulation, ♀♀ will eject up to 300 ml of the ejaculate. Sperm competition and female promiscuity within the species is thought to lead to the large volume of seminal fluid (Klingel 1974, Ginsberg 1989, Ginsberg & Rubenstein 1990).

Foaling has rarely been observed and is assumed to occur primarily at night and away from the herd. Lactating mares and newborn foals rapidly join a nursery herd that remains as close to water as possible. These nursery herds can be stable for up to three months, but in areas where water and grazing are separated by large distances (e.g. in areas where the areas close to water are heavily overgrazed), they tend to be less stable.

Grévy's Zebra *Equus grevyi* braying; note whiskers.

Grévy's Zebra *Equus grevyi*.

Play in foals occurs only when they are in good condition (Rowen 1992). Thus, in the late dry season or droughts, or in overgrazed habitats, play is rarely seen. Unlike other equid species, allogrooming is very rare among individuals of this species.

Vocalizations in reproductive classes other than territorial ♂♂ are uncommon. Bachelor ♂♂ rarely vocalize (J. R. Ginsberg pers. comm.). Mares that become separated from their foals will call with a soft bray, similar to that of the territorial ♂♂, but quieter and without the strangulated squeak (S. D. Williams pers. obs.). When returning from water, mares will also call and their foals will answer (Klingel 1974, S. D. Williams pers. obs.).

Reproduction and Population Structure Breeding is highly dependent on stochastic patterns of climatic variation (Ginsberg 1988, Williams 1998). Females in poor body condition enter anoestrus during times of low resource availability (Ginsberg 1989). A peak in oestrus among ♀♀ follows the onset of high resource availability (usually the wet season), which results in a peak in births 13 months later (Williams 1998).

Over 90% of recorded copulations are by territorial ♂♂ (Ginsberg 1988). Levels of urinary androgens are higher in territorial ♂♂ than for either non-breeding ♂♂ or breeding ♂♂ that abandon their territories. Urinary androgen concentration for a territorial ♂ is, in

Grévy's Zebra *Equus grevyi*.

turn, negatively correlated with the time since ♀♀ last visited his territory (Chaudhuri & Ginsberg 1990).

Gestation period is 58 (range 55–61) weeks (King 1965). Mares give birth to a single foal (probably more often at night) and come into oestrus between 6 and 15 days post-parturition. Oestrus lasts 4–7 days (Asa *et al.* 2001). If they are not impregnated, they will continue to cycle every 27 days ($26.8 \pm \text{S.E. } 0.28$, $n = 9$; Bennett 1980, Ginsberg 1989), but longer in captive animals (28–35 days, Asa *et al.* 2001). Because breeding is dependent on climatic conditions, inter-birth intervals are highly variable. Mean inter-birth intervals for Grévy's Zebras have been recorded as 16.2 months (Williams 1998).

Lactation can continue for up to a year, but most foals are weaned by an average of 11.4 months (Becker & Ginsberg 1990, Rowen 1992). Foals stay with their mothers for up to two years. Wild zebras mature and breed later than captive animals. The youngest first foaling in captivity was recorded at three years and four months (Asa *et al.* 2001). In the wild, ♀♀ may breed only slightly later than captive animals. In contrast, ♂♂ that take over territories are thought to do so only when they are approximately seven years old (Ginsberg 1988).

It is thought that there is an equal sex ratio at birth. However, because of the increasing foal mortality, the mean mare : foal ratio is high (2.74 mares for every foal over a three-year study; S. D. Williams pers. obs.).

Sources of mortality have not been fully determined. However, recent studies have shown that juvenile mortality is critical (Williams 1998). Foal survival has been directly related to the extent to which their mothers move: there is low foal survival when mares make large or frequent small-scale movements (Rowen 1992, Williams 1998). This supports the suggestion that foals are energetically constrained.

One wild-born specimen was about 31 years old when it died in captivity (Weigl 2005).

Predators, Parasites and Diseases In areas where densities of Lions *Panthera leo* are high, such as on the Laikipia Plateau and on the Lewa Wildlife Conservancy, their impact on Grévy's Zebra populations is profound (D. I. Rubenstein pers. comm.). Outside of these areas, the impact of predation is largely unknown, although it is probably low as predator densities – including Lions – are reduced due to poisoning campaigns (using acaricide) by pastoral people (S. D. Williams pers. obs.). None the less, in these areas, Cheetahs *Acinonyx jubatus* and

Spotted Hyenas *Crocuta crocuta* are known to take foals, and Nile Crocodiles *Crocodylus niloticus* take adults (Rowen & Ginsberg 1992, S. D. Williams pers. obs.). In addition, in areas with pastoral people, water sources are generally monopolized during daylight hours. This excludes zebras, which are, therefore, forced to drink at night. This exposes unprotected foals in kindergartens to nocturnal predators.

Little is known about diseases that affect Grévy's Zebras, but Muoria *et al.* (2007) recorded an outbreak of anthrax in the Wamba area of southern Samburu, Kenya, between December 2005 and March 2006, during which 53 Grévy's Zebra succumbed to anthrax. Babesiosis has been recorded in a free-ranging animal due to transmission from the tick *Rhipicephalus evertsi* (Pipano & Tadmor 1978). Muoria *et al.* (2005) examined faecal samples of Grévy's Zebra for gastrointestinal parasites, and found *Trichostrongylus* sp. present in 78% of the samples; other parasites occurring in high frequencies were *Oesophagostomum*, *Haemonchus contortus* (which is highly pathogenic to small ruminants), *Entamoeba coli* cysts and *Balantidium coli* cysts. Data on the impact of these species on Grévy's Zebra are lacking. Endoparasite loads are particularly great when animals are in poor condition (S. D. Williams pers. obs.).

Conservation IUCN Category: Endangered A2ac. CITES: Appendix I. CMS: Appendix I.

Legally protected in Ethiopia. Protected by hunting ban since 1977 in Kenya. The range of Grévy's Zebra has shrunk dramatically as a result of hunting (Ethiopia, Somalia and E Kenya), exclusion from water sources by pastoral people and habitat loss through vegetation change and erosion that result from overgrazing (throughout their range). It has been suggested that hunting for skins in the late 1970s may have contributed to the decline in Kenya (R. Elliott pers. comm.). However, since the CITES listing in 1979, the killing of Grévy's Zebras for their skins seems to have ceased. Recent data suggest that the decline in Kenya is continuing although at a slower rate because recruitment is very low due to low juvenile survival. This is a result of competition for resources – both food and access to water – with pastoral people and domestic livestock (Williams 1998). However, there remains a low level of hunting of Grévy's Zebras for food and, in some areas, medicinal uses (S. D. Williams pers. obs.). In Ethiopia, by contrast, killing of Grévy's Zebras using abundant semi-automatic weapons is the primary cause of the decline.

Besides exclusion of Grévy's Zebras from water sources by pastoral people, the water supply in critical perennial rivers has also declined, most notably in the Ewaso Ng'iro R. in Kenya, where over-abstraction of water for irrigation schemes has reduced dry season river flow by 90% over the past three decades (Williams 2002). This leads to dramatic reduction in the dry season range of Grévy's Zebra (Williams 1998). In contrast, Grévy's Zebras are increasing in numbers on the Laikipia Plateau in Kenya, which, historically, may have been a marginal area for them (Williams 2002). In these areas (and particularly the Lewa Wildlife Conservancy), they are protected and competition with domestic livestock is reduced as cattle are managed to favour wildlife. They have, therefore, been successfully increasing since they first expanded into this area in the early 1970s.

The conservation of Grévy's Zebra and its fragile arid ecosystem are inseparable. For the continued survival of Grévy's Zebra, it is imperative that critical resources on which the zebras depend remain accessible and sufficient to meet their nutritional requirements.

This is predominately dependent on activities of agriculturalists in highland areas and pastoral people in lowlands. These people determine levels of water abstraction for irrigation and domestic livestock management and stocking rates, and thus, by extension, the range and growth, respectively, of Grévy's Zebra populations.

Hybridization with Plains Zebra has been discussed as a potential threat to Grévy's Zebra in Laikipia, although Cordingley *et al.* (2009) argue that, based on behavioural observations, this is unlikely to dilute the Grévy's Zebra gene pool in the short term.

It is also essential that the small, isolated populations of N Kenya and S Ethiopia are protected. Community conservation approaches are probably the best means of achieving some level of protection. At present, protected areas form less than 0.5% of the range of Grévy's Zebra. In Ethiopia, the protected areas are only nominal (Alledeghi Wildlife Reserve, Yabello Sanctuary, Borana Controlled Hunting Area and Chalbi Sanctuary). In Kenya, the Buffalo Springs, Samburu, Shaba N. R. complex and the private land wildlife conservancies on the Laikipia Plateau provide a core and crucial protection of Kenya's southern population of Grévy's Zebras. These areas will be increasingly important to their persistence (Williams 2002). Other protected areas in Kenya appear to be ineffective. These include Sibilo N. P., where

they are now rare, and the nominal Losai N. R. The Grévy's Zebras that were translocated to Tsavo (Tsavo East in 1964 and Tsavo West in 1977) have not been seen in either protected area for some years and only a small number (<20) have been seen in ranches to the east of the National Parks.

Stuart D. Williams

Equus quagga PLAINS ZEBRA (COMMON ZEBRA)

Fr. Zèbre des Plaines; Ger. Steppenzebra

Equus quagga Boddaert, 1785. Elenchus Animalium 1: 160. 'Caffrorum regione'; locality paralectotype now identified as Seekoei R., Colesburg District, Northern Cape Province, South Africa (Grubb 1999).

Plains Zebra *Equus quagga* *crawshaii*.

Taxonomy The close genetic relationship of the true Quagga with other Plains Zebras (for which the name *E. burchellii* is commonly used) has been established, indicating the desirability of extending the species *E. quagga* to include all Plains Zebras (Rau 1978, 1986, 1997, Higuchi *et al.* 1984, George & Ryder 1986, Harley 1988, Leonard *et al.* 2005;

but see Bennett 1980, Klein & Cruz-Urbe 1999). Type localities, anatomical details and general characters are given by several authors, including Pocock (1902), Antonius (1951), Grubb (1981, 1999), Groves & Ryder (2000), Groves (2002) and Groves & Bell (2004).

Plains Zebra *Equus quagga*.

A revised subspecies classification, long under discussion (e.g. Ansell 1974, Grubb 1981, Groves & Ryder 2000, Groves 2002), was presented by Groves & Bell (2004), who recognized six subspecies, based on coat patterns, skull metrics (see Measurements) and the presence or absence of a mane and of the infundibulum on the lower incisors. Intergrades are observed. However, molecular studies involving mtDNA and microsatellites failed to distinguish between the six described subspecies and no structuring was found that might be indicative of localized evolutionary units (Lorenzen *et al.* 2008). The latter authors remarked that Plains Zebra showed the lowest overall differentiation recorded in any African ungulate studied so far. The only other species showing a similar absence of genetic structuring is the African Buffalo *Syncerus caffer*, but which lacks the high levels of morphological variation present in the Plains Zebra.

Synonyms: *annectans*, *annectens*, *antiquorum*, *boehmi*, *borensis*, *burchellii*, *burschellii*, *campestris*, *chapmani*, *chapmanni*, *couagga*, *crawshaii*, *crawshayi*, *cunninghamei*, *danielli*, *elongatus*, *festivus*, *foai*, *goldfinchi*, *granti*, *greyi*, *isabella*, *isabellinus*, *jallae*, *kaokensis*, *kaufmanni*, *lorenzi*, *lylei*, *mariae*, *markhami*, *mauretanicus*, *muansae*, *paucistriatus*, *platyconus*, *pococki*, *qouagga*, *quaccha*, *selousi*, *simplex*, *simplicissimus*, *tabeti*, *tigrinus*, *transvaalensis*, *trouessarti*, *typicus*, *wahlbergi*, *zambeziensis*, *zebroides*. Chromosome number: $2n = 44$; there are 17 pairs metacentric and four pairs acrocentric autosomes, and the X chromosome is submetacentric while the Y is a small acrocentric chromosome (Benirschke *et al.* 1963, Heinichen 1969a, 1970, Hsu & Benirschke 1971). Compared with Grévy's Zebra *Equus grevyi*, the Plains Zebra

Lateral, palatal and dorsal views of skull of Plains Zebra *Equus quagga*.

has an extra pair of metacentric chromosomes, but lacks two acrocentric pairs.

Description Muscular equid with relatively short neck, sturdy legs and characteristic striping. Ears are pointed, muzzle is comparatively blunt and tapered. Mane varies from thick and long to short and thin, and sometimes is absent altogether. Stripe patterns are prominent in the northern subspecies, but less so in the south; shadow stripes, brownish stripes between the dark stripes, are thin or absent in the north and wide and prominent in the south. Ground colour is white in the north and cream or buffy in the south. Forelock and mane are thin to absent in the northernmost populations, e.g. Kidepo N. P. in NE Uganda and SE Sudan, and well developed in the southern populations. Body stripes are broader than in Grévy's Zebra and the Mountain Zebra *E. zebra*, although less so in the Cape Mountain Zebra *E. z. zebra*, which has particularly wide stripes on the rump; rump stripes do not meet the dorsal mid-line, while in the northern populations, and many individuals in the southern populations, the stripes extend to the ventral mid-line. Very light individuals with pale stripes only (but not albinos), as well as melanistic individuals with reduced stripe patterns, occur. The basic character of the stripe patterns, width, simplicity versus complexity, i.e. forks, spots, short stripes, is inherited (H. Klingel pers. obs.). Patterns from various subspecies and populations are published in Cabrera (1936), Antonius (1951), Rau (1974, 1978), Kingdon (1979, 1997) and Schürer (1999). Stripe patterns are individually unique and photographic file card systems have been used successfully for identification in the field (Klingel 1965a, 1967). Legs are striped to the hooves in northern populations, but not, or not clearly, in southern ones. Anterior part of tail without tail hair (as in all equids except the horse). There is little sexual dimorphism, although stallions average slightly larger than mares and with thicker necks. One pair of nipples.

Braincase large, forehead markedly convex, with relatively thick and broad zygomatic arches. Ear bullae small relative to the size of the skull; paroccipital process thick and well developed. Postorbital constriction relatively narrow. Mandible massive, deep and wide. The premaxilla curves downward below the level of the alveolar line of the

cheekteeth (Grubb 1981, Groves 2002). Males have larger spade-shaped canines, whereas in mares the canines are lacking or vestigial. Upper incisors have infundibular patterns that change shape with wear and eventually disappear; in the lower incisors, these patterns are absent or reduced to a simple cup in most northern populations, but more usually present in southern ones. Molars deeply hypsodont. Tooth eruption and wear patterns are similar to those of the Horse *Equus ferus* – the first molar is the first tooth to develop, the third incisor the last – and have been used for ageing (Erz 1964, Klingel 1965b, Klingel & Klingel 1966b, Smuts 1972, 1974a).

Geographic Variation

E. q. crawshayi (including *annectens*, *foai*) (Crawshay's Zebra): Zambia, east of the Luangwa R., Malawi, SE Tanzania from L. Rukwa east to Mahungoi, and Mozambique as far south as the Gorongosa district. Large size; stripes numerous and narrow, with five or more stripes meeting the belly stripe; shadow stripes absent, and leg stripes complete and unbroken to hooves; body tone white to off-white; infundibula on lower incisors absent or reduced to a cup.

E. q. borensis (Half-maned Zebra): NW Kenya, from Guas ngishu and L. Baringo to the Karamoja district of Uganda and SE Sudan, east of the Nile R. to the northern limit of the species at 32° N. Similar to *E. q. boehmi*, but larger, more sexually dimorphic, and mane absent or reduced in adult ♂♂; short diastema, and infundibula, on limited evidence, seem to be absent.

E. q. boehmi (including *cunninghami*, *goldfinchi*, *granti*, *isabella*, *jallae*, *mariae*, *muansae*, *zambeziensis*) (Grant's Zebra or Boehm's Zebra): Zambia, west of the Luangwa R., west to Kariba, Shaba Province of DR Congo north to Kibanza Plateau; Tanzania north from Nyangau and Kibwezi into SW Uganda, SW Kenya as far as Sotik, and E Kenya, east of the Rift Valley, into S Ethiopia and perhaps to the Juba R., Somalia. Smallest subspecies; striping pattern broad, with stripes down to hooves; shadow stripes poorly expressed or absent; infundibula on lower incisors often absent. The small, entirely maneless zebras of the Juba region, Somalia, may prove to be a separate subspecies.

E. q. chapmani (including *kaufmanni*, *markhami*, *pococki*, *selousii*, *transvaalensis*) (Chapman's Zebra): NE South Africa, from about 24° S, 31° E, north to Zimbabwe, west into Botswana at about 19° S, 24° E, the Caprivi Strip in Namibia, and S Angola. Largest subspecies; ground colour not pure white; legs striped thinly to the hooves; shadow stripes prominent on haunches, and usually on neck; snout short and narrow; infundibulum usually cup-like but may be complete.

E. q. burchellii (including *antiquorum*, *campestris*, *festivus*, *isabellinus*, *kaokensis*, *paucistriatus*, *typicus*, *zebroides*) (Burchell's Zebra): formerly north of the Vaal and Orange Rivers, extending north-west via S Botswana to Etosha N. P. and the Kaokoveld in Namibia, south-east to KwaZulu–Natal and Swaziland. Now extinct in middle of range. Stripes reach haunches, sometimes upper parts of limbs; one or two shadow stripes on haunches; small, narrow skull with broad, long marston. Size increases from south-east (KwaZulu–Natal) to north-west (Etosha N. P.); Etosha zebra are nearly as large as *E. q. chapmani*.

E. q. quagga (including *couagga*, *danielli*, *greyi*, *lorenzi*, *quagga*, *quaccha*, *trouessarti*) (Quagga): former Cape Province, south of the Orange and Vaal Rivers and west of the Drakensberg; extinct since

Quagga *Equus quagga quagga*.

the end of the nineteenth century (ca. 1883). Stripes only on neck and back, legs unstriped and white; ground colour dark cream to brown (Pocock 1902, Cabrera 1936, Antonius 1951, Ansell 1974, Groves 2002, Groves & Bell 2004; for colour plate see Kingdon 1979 and Smithers 1983).

Plains Zebras have in the recent past been re-introduced in many farms and protected areas in southern Africa. The stock was often taken from different populations disregarding the subspecific identities and producing an undesirable and unnatural mix. Breeding groups of these mixed types have also been exported to zoological gardens.

Similar Species

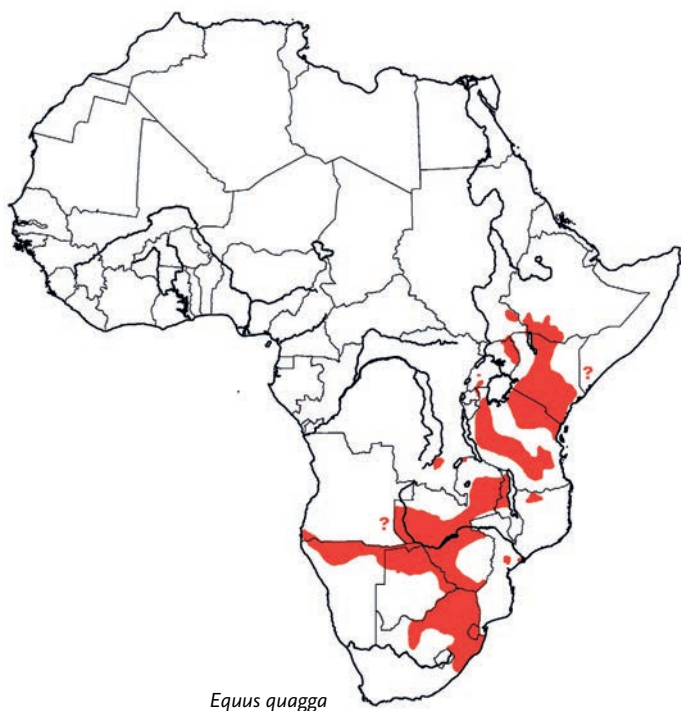

Equus zebra hartmannae. Slightly bigger; dewlap present; narrow black stripes on white background, with grid-iron pattern across rump; belly white; ears pointed. Namibia, esp. Naukluft, Namib, Kaokoveld.

E. z. zebra. Smaller than *E. z. hartmannae*, ♂ smaller than ♀ (the size of a KwaZulu–Natal *E. q. burchellii*); broader muzzle, longer diastema and nasal bones, very broad black stripes and narrow white interspaces. Western Cape and Eastern Cape of South Africa.

E. grevyi. Much larger; fine stripe pattern; adults with black, young with brownish stripes on off-white background; prominent dark dorsal stripe with longer hair; big round ears. N Kenya to S Ethiopia.

Smuts & Penzhorn (1988) describe a number of structural differences between the skulls of the Plains and Mountain Zebras in detail; most important is the uniquely rectangular shape of the foramen magnum. Differences between Plains and Hartmann's Zebras are described by Eisenmann & de Giuli (1974).

Distribution The Plains Zebra is one of the more successful African ungulates, ranging from S Sudan and S Ethiopia to N Namibia and N South Africa (and formerly south of the Orange and Vaal Rivers to the Cape). The species is now extinct in two countries in which it formerly occurred, namely Lesotho and Burundi; there is no current information on their status in Angola where they may also be extinct (Hack *et al.* 2002). In the recent past, Plains Zebras have not occurred west of the Nile R. However, from the early Pliocene

Equus quagga

to the Holocene the species extended over almost the whole African continent. Fossil remains are known from North Africa (Morocco, Algeria, Tunisia, Mali, Libya) to the Cape (Churcher & Richardson 1978).

Habitat Suitable habitats include grasslands and grassland–bushland mosaics (from humid to mesic environments); also present in miombo woodland. On Mt Kenya, Plains Zebras occur up to 4300 m, and individual home-ranges can cover up to 1000 m in altitude (Coe 1972; see also Young & Evans 1993). Absent from the Congo basin rainforest, and from dune desert. Water is an essential habitat requirement, and they seldom move more than 12 km from water sources.

Abundance Locally common throughout its range in protected areas, but also outside protected areas, especially in Kenya and Tanzania. Total numbers may be in the region of 660,000, possibly up to 1 million, with some 200,000 Plains Zebras in the greater Serengeti/Mara ecosystem in N Tanzania and adjacent Kenya (East 1997, Hack *et al.* 2002). The Serengeti migratory subpopulation of >150,000 individuals concentrates during the rains from Nov to May in the Serengeti plains. At the beginning of the dry season in Jun it migrates to the western and northern parts of Serengeti N. P. and adjacent areas, and into Masai Mara National Reserve in Kenya. During the migration it overlaps to some extent with resident populations (1) of the western Serengeti N. P., (2) of the Masai Mara National Reserve in Kenya, and (3) of the Loliondo area north-east of the Serengeti N. P. During the rains, in the Ol Balbal depression south-east of the Serengeti plains, it overlaps with parts of the Ngorongoro population that have moved in from the Crater (Klingel 1969a, pers. obs.). Besides the Serengeti/Mara ecosystem, other current major populations are those in: Kajado/Amboseli (Kenya) – 50,000; Manyara/Tarangire (Tanzania) – 40,000; Laikipia (N Kenya) – 33,000; and Kruger N. P. (South Africa) – 31,000.

Densities range from 0.9/km² in Kruger N. P. (Smuts 1976a) to 22/km² (ground count) (Klingel 1967) and 19.2/km² (aerial

Grant's Zebra *Equus quagga boehmi* illustrating variations in width of stripes.

count) in Ngorongoro (Turner & Watson 1965). Density figures for the Serengeti are 5.8–8/km² (Kingdon 1979, H. Klingel pers. obs.).

For two East African populations, the limiting factors of population size have been identified. In the Serengeti, zebras appear to be limited by high foal mortality; the high predator/prey ratio suggests that predation may be the decisive limiting factor (Grange *et al.* 2004; and see Gasaway *et al.* 1996). In Laikipia, in N Kenya, with a low predator/prey ratio, population size is correlated with rainfall (Georgiadis *et al.* 2003).

Adaptations Disruptive coat pattern is thought to serve as camouflage in bushland and in dim light. In open terrain the air vibration during the heat of the day makes Plains Zebras over some distance less conspicuous to the human eye than uni-coloured antelopes of similar size, such as Common Wildebeest *Connochaetes taurinus*. However, it is not known whether the stripes give Plains Zebras an advantage over other species. In Kruger N. P., Lion *Panthera leo* predation affected Common Wildebeest more severely than Plains Zebras (Mills & Shenk 1992). It has been speculated that striping may confuse attacking predators, although this is not based on observation. At close range the stripe pattern might allow for individual recognition among group members. This is especially obvious when foals that have been left behind are searching for their mothers. They walk from one family to the next, often performing naso-nasal contact, but when near their own family they just head straight for the mother and start sucking – without prior sniffing (Klingel 1967). Recognition by olfaction alone can probably be ruled out. The stripes may protect to some extent against *Glossina* sp. and other biting flies, which prefer uniform white or black

models over striped ones. Protection is only relative as olfactory attractants for the flies are crucial (Waage 1981) and the zebras are nevertheless infected with *Trypanosoma* spp. (Baker *et al.* 1967).

Skin and surface temperatures of the black stripes are much higher than of the white ones, but the stripe pattern has no function for thermoregulation; in terms of temperature regulation, the zebra is a 'grey' coated animal (V. Finch pers. comm.). Using infra-red photography, Cena & Clark (1973) recorded surface temperatures of 39°C for the black and 30°C for the white stripes, whereas recent studies using the same method (Benesch & Hilsberg 2003, Benesch & Hilsberg-Merz 2006) measured 62.5°C and even 71.9°C for the black and 41.6°C for the white stripes of a zebra exposed to direct sunshine. In the dark the black and white surface temperatures were almost identical; however, the black stripes were slightly (0.5–0.7°C) below the white stripes.

From a selection of hypotheses on the function of stripe patterns, Ruxton (2002) analysed and dismissed some while suggesting further experimental approaches. With the exception of individual recognition, all these suggestions assume selection by forces external to the animals themselves. However, Kingdon (1979, 1997) has suggested stripes evolved as a consequence of intra-specific social selection. He suggested that basic susceptibilities of the neurovisual system have been enlisted to receive and transmit socializing stimuli (see genus *Hippotigris*).

Fuller *et al.* (2000) measured brain and arterial blood temperatures in three free-ranging Plains Zebras in their natural habitat, and found that brain temperature consistently exceeded blood temperature, on average by 0.2–0.4°C, and that changes in brain temperature closely tracked changes in blood temperature. There was no evidence of selective brain cooling, even during hyperthermia associated with intense, short-duration exercise. This relationship between brain and arterial blood temperatures in free-ranging zebras was unlike that reported for horses.

As family groups are fully reproductive non-territorial units, they are unrestricted in their movements and thus capable of colonizing new ranges. Plains Zebras are maladapted to drought situations: during a prolonged drought in the early 1970s populations in N Kenya were completely wiped out and others severely reduced whereas Grévy's Zebras in the overlap zone hardly declined at all. Although the two species have basically different types of social organization, physiological differences like the tolerance of saline water are likely to be the cause of different levels of mortality (Klingel 1974).

Foraging and Food Plains Zebras are primarily grazers: over 90% of its diet consists of grass the rest being herbs, which may be taken by accident. In Kruger N. P., Smuts (1972) recorded a list of some 50 species of grass and eight herbs. The choice of grass species broadly reflects the species available, but zebras do show some selectivity: of seven major grass species, one, *Panicum maximum*, contributed 40% of the intake and the same preferences were shown all through the year (Ben-Shahar 1991). Other favoured grass species in studies include *Themeda triandra*, *Cynodon dactylon* and *Eragrostis superba* (Grubb 1981). In extreme dry periods they resort to browse and even to corms and rhizomes (Pienaar 1963, Tinley 1966, Gwynne & Bell 1968). Plains Zebras appear to favour areas of short grass, particularly recently burnt areas with a new flush of growth. However, in the Serengeti, Plains Zebras are the first in a grazing succession. They move into the long grass, grazing it down by feeding mostly from the top stratum

(using their incisors, rather than plucking) and thereby making it attractive to the Common Wildebeest and other more selectively feeding species (Vesey-Fitzgerald 1960, Gwynne & Bell 1968, Bell 1971, Maddock 1979). Considerable overlap in the use of grass species by Common Wildebeest and Plains Zebras was recorded in the Sabi-Sand G. R. in South Africa (Ben-Shahar 1991). In the dry seasons zebras feed mostly on fibrous grass stems (>50% of the diets), which are avoided by other grazers. The diet is fibrous and low quality, but this is compensated for by their ability to eat larger quantities than ruminants; data on horses suggest that this is a result of a faster passage time in the gut (Duncan *et al.* 1990).

In several areas, Plains Zebra movements are directly correlated with the availability of water. They move to grazing areas during the rains and concentrate near permanent rivers or pools during the dry season. Examples are the Rukwa flood-plains, which are suitable only after they have fallen dry (Vesey-Fitzgerald 1965), the Tarangire N. P./Simanjiro Plains system in N Tanzania (Kahurananga & Silkiluwasha 1997) and Makgadigadi Pans G. R. in Botswana (Kgathi & Kalikawe 1993). A similar situation prevails in the Sudd in S Sudan. During the rains the zebras stay on high, dry ground. During the dry season and after the big fires they move close to the river and feed on the fresh growth of *Vossia*, which is an extremely coarse swamp grass and can only be grazed by a hard-hoofed animal during the period when deep, soft soils are no longer waterlogged (J. Kingdon pers. comm.).

Social and Reproductive Behaviour Plains Zebras live in social groups: (1) family (or harem) groups consisting of one stallion, one to several mares and their young, and (2) stallion groups. Some adult ♂♂ are solitary. This type of social organization is exceptional among the ungulates, the only African parallel being the closely related Mountain Zebra (Klingel 1968a, 1969c, Joubert 1972a, Penzhorn 1984a). Family group sizes in the various populations studied ranged from two, i.e. a stallion and a mare, to 16, and averages were from 4.2 and 4.5 in Kruger N. P. (Klingel 1967, Smuts 1976a, b) to 4.7 in Etosha N. P. (Klingel 1969a; and see Gasaway *et al.* 1996) to 7.7 in the Ngorongoro Crater (Klingel 1967, 1969a). The maximum numbers of mares per family ranged from four to six, and population averages were from 2.2 and 2.3 in Serengeti N. P. and Etosha N. P., respectively (Klingel 1969a), to 2.8 in Ngorongoro (Klingel 1969a). Thus, family size differences are largely caused by different portions of subadults and foals in the families (Klingel 1965a, 1967, Smuts 1976a, Monfort & Monfort 1978).

In an investigation of social organization and behaviour in Ngorongoro, more than 600 individually known Plains Zebras were monitored for up to 28 months, using a photographic file-card system. In addition, 122 key individuals were marked with brands and ear tags for quick recognition in the population of 5500 (Klingel 1965a, 1967, 1969a). The family groups were found to be stable social units with respect to the adult members. Apart from rare exceptions, the mares stay on until they die. Stallions are equally attached to their groups, but are replaced by stronger ones when old, weak, wounded, or after death, in this study at the rate of 9% per year. Sick, weak and injured group members are looked after, and the group waits for them, or group members walk back to lead the way. A stallion even grasped with his teeth a sedated mare (after immobilization) by the skin of her neck and led her back to the group (Klingel 1967). The family stallion has the mating rights over his mares. Extra-group matings were not observed.

Group fidelity of the mares, who are unrelated, is independent of a stallion's presence, and the group stays intact even when the stallion has been killed and a new stallion has not yet taken-over.

Adolescents leave their parental groups in a set pattern. Fillies leave at age 1 to 2½ years during oestrus. Departure is not voluntary: they are abducted by other stallions. The family stallion tries to prevent abductions, and often violent fighting ensues. Depending on the number of suitors – 18 in one observed case – the family stallion can succeed for some time to keep his daughter in the group but will eventually be exhausted and defeated. The filly usually does not stay with her first suitor and the same process repeats itself with the next oestrus. The attractive signal is the oestrous stance of the adolescent mare, hindlegs apart and tail lifted. Under the influence of an immobilizing drug (etorphine hydrochloride, M99) young and adult Plains Zebras displayed a similar stance and thereby attracted stallions from the vicinity who fought each other, tried to herd the semi-immobilized individual away and even mounted it – irrespective of its sex. After the drug had worn off the stallions lost interest.

Suitors of adolescent mares are family stallions who thereby enlarge their families, or bachelors who start a family. New family members are initially rejected by the established mares, but they are protected and herded by the stallion and eventually they are integrated. Adult mares display the oestrous stance only just before copulation, thus other stallions are not attracted and she stays with her stallion.

Young stallions leave their parental group at 1–4 years of age, and join other stallions. Departure is voluntary, and there is no antagonism by the family stallion or any other member of the group. On the contrary, the family stallion and the young stallion's mother search for the son and try to bring him back when he has separated. Stallion groups are variable in numbers and composition, but small core groups of two or three are stable over many months. Some groups consist of fully grown adults who in turn are joined preferentially by other adults; in other groups adults and subadults join up. Displaced family stallions were joined by sons and long-term stable associations formed (Klingel 1967).

Families and stallion groups maintain their integrity even when mingling freely with other groups in the grazing areas, on migrations, at waterholes and in the large herds of thousands and tens of thousands of conspecifics as in the Serengeti. Individuals that lose contact, search for their group and are in turn sought by other members of their group. In the family, stallions are sought by mares, foals and subadults; subadult stallions by the family stallion; and foals by their mothers, their father and the rest of the family. During the day searches are mostly by sight; there is strong evidence that zebras recognize group members from the stripe pattern, and, at close range, also by smell. At night, and in more confusing situations or at long range, zebras make contacts by calling. Calls are individually different and recognizable to the human observer and presumably to conspecifics.

Group members perform social grooming, especially of neck and shoulders, which cannot be reached with their own mouths. In families, preferred grooming partners are mares and their own foals, stallions and selected mares, but not mares with other mares. Grooming preferences are also obvious in stallion groups. Plains Zebras like to rub themselves on termite hills, rocks, logs and trees and also like to roll on the ground while taking dust baths.

A dominance order exists in the family groups with the stallion being the alpha individual. He defends the members of his group

against competitors and predators and can direct the group's movements, although he normally brings up the rear. Leadership is vested in the highest-ranking mare. When migrating the mares follow her in the order of their rank, the lowest ranking one being last. The foals walk behind their respective mothers, youngest first. Family stallions are of equally high rank, and higher than bachelors, and as long as they are healthy their position is not challenged.

Like all equids, fighting in Plains Zebras is relatively unritualized, employing hooves and teeth. Because of the bluntness of their weapons they can inflict only minor injuries like torn or bitten-off ears. In intra-specific fights the stallions employ several techniques: (1) neck-wrestling, each trying to get his neck above the other's and push him down; (2) biting match, with bites aimed at head, neck, ears, legs of partner; (3) circling, when each protects his legs from being bitten and they both come to a sitting position; (4) rearing on hindlegs, flailing with the forelegs and trying to get the other off balance, combined with biting; (5) chasing the loser, combined with biting; and (6) kicking as a defence when fleeing. Mares fight mostly by kicking with their hindlegs, but also snap at conspecifics (e.g. when trying to get to water).

Plains Zebras are non-territorial. They live in overlapping home-ranges with seasonal shifts depending on the availability of food and water. In the Serengeti, seasonal home-ranges of the migratory population are in the order of 400–600 km², and annual ranges can be estimated at more than 2000 km² (Klingel 1969b, pers. obs.). In Ngorongoro Crater total annual home-ranges were from 80 to 250 km², the latter being the total crater floor surface. Although sedentary, during the rains, up to one-third of the population moves out of the Crater to the adjacent Ol Balbal depression where they mingle with the migratory Serengeti zebras. However, at the end of the rains the two populations separate and the animals move back to where they have come from. Some exchange, in particular of adolescent mares, is thought to take place, but has so far not been documented (Klingel 1967, 1969a). Home-ranges in Kruger N. P. are from as little as 49 to as much as 566 km² (Smuts 1975a); within the home-range, there are foci of activity around water supplies, while other areas are used less frequently.

Feeding takes ca. 50% of the time, the rest being expended resting and moving. In the evenings the Plains Zebras in Ngorongoro Crater congregate in areas of short grass growth where they spend the night. Three resting periods are observed during which at least one member of a family group stands upright as a sentinel whereas the others lie semi-recumbent or flat on their sides. In the mornings the zebras move to other grazing areas and/or to water, following a regular pattern for weeks; they shift when the ecological conditions change. Daily movements were up to 26 km per day (Klingel 1967, 1969a). Annual movement of the Serengeti population is on the order of several 100 km (Maddock 1979).

Zebra herds in the Serengeti and in the Ngorongoro Crater are anonymous aggregations with the family and stallion groups as units, and no higher level of social organization is evident. Although the herd as a whole grazes in a particular area or moves and migrates in a given direction, the groups move independently of each other. They may leave the herd and later join the same or another one, without regard to previous neighbours and there was no indication of individualized relationships beyond the families and stallion groups (Klingel 1967, Rubenstein & Hack 2004). However, in a

Grant's Zebra *Equus quagga boehmi*.

low-density situation in the Samburu–Buffalo Springs Reserve in N Kenya, Rubenstein (1986) discovered a multi-level individualized relationship as some family groups associated preferentially.

In the Crater, family groups and stallion groups segregate to a certain extent, the stallions keeping more to the slopes, the families more to the floor (Klingel 1967). This feature can distort sex ratio assessments. Sexual segregation has also been observed in the Serengeti population (R. D. Estes pers. comm.).

Plains Zebras establish naso-nasal contacts with conspecifics. In the families, contacts are between all members. During the day, family stallions leave their families several times to contact peers in the vicinity and to perform a greeting ceremony. After the naso-nasal contacts they sniff each other's genitalia, then resume naso-nasal contacts and eventually make a final jump or a jerk with the head, after which they separate and each walks back to his mares. There is no overt aggression in these encounters.

Both bachelor and family stallions perform elaborate defecation ceremonies. When one of them defecates, they all gather around the fresh dung pile, sniff, perform flehmen (lip-curl) and defecate. All present usually do the same, producing a communal dung pile. Often they all start sniffing and flehmen simultaneously, perform naso-nasal contacts and continue playfully with the greeting ceremony, repeating the various sequences again and again.

During oestrus, and rarely at other times, the family stallion monitors the mare's excretions. He walks up to the place, or he waits behind the mare until she has performed. He then sniffs the defecations and urinations, displays flehmen and marks defecations with dung and/or urine, and urinations with urine. The significance of this behaviour remains obscure, especially as it is inconstant and as other stallions ignore the excretions, marked or unmarked, and ignore the stallion's behaviour.

During oestrus mares display an oestrous face (see later) and posture with hindlegs apart and tails slightly raised. This posture is most conspicuously displayed by adolescent mares (see above) and attracts suitors. Oestrus lasts for about a week during which the stallion is in close attendance. Copulations occur during the 1–2 days of high oestrus, before and after the mare kicks the stallion with her hindlegs and prevents mounting by moving forward in a trot or canter. During high oestrus the mare stands, pushes backwards against the stallion, and permits mounting and intromission. Mountings are at intervals of 20–70 min, and several copulations occur during the day (Klingel 1968b).

Birth takes place with the mare lying flat on her side. The foal is expelled head first, and initially fully enclosed by the embryonic membranes. It extricates itself from these without help. A foal can stand after 11 min, make first steps after 19, walk after 34 (and canter

Grant's Zebra *Equus quagga boehmi* showing proportions of a young foal.

after 44), and suck after 67; it drops the meconium after 97 min. The afterbirth is dropped within 1½ h after parturition. The mare licks the foal; she chews the afterbirth and embryonic membranes but does not eat any of it. The stallion stays nearby and watches closely. The rest of the group continues grazing and seems to be indifferent. However, they stay in the vicinity and wait for mare and foal to join them (Klingel & Klingel 1966a).

During the first few days after giving birth, the mare threatens and chases all other members of the group, including her own older offspring and the family stallion, as well as any other zebras. This behaviour is also known from other equids and other ungulates and is considered to be correlated with the critical period of imprinting. It ceases after about ten days and then all members of the group contact the foal, which by then obviously recognizes its mother.

Infanticide has been observed in captive Plains Zebras in the form of induced abortion (feticide) and physical attack of the neonate by a new stallion (Pluháček & Bartoš 2000, Pluháček *et al.* 2006). In the Crater population a number of takeovers were recorded of groups with highly pregnant mares and very young foals, but no instance of successful or attempted infanticide was observed (Klingel 1967). Only one case of infanticide has been reported from the wild, by a tourist in Etosha N. P. in Namibia (Heinrich 1996); status of the infanticidal stallion as well as circumstances are unknown.

Plains Zebras (like the other equids) command a rich repertoire of visual and acoustic signals and expressions (Klingel 1972, 1977b). The contact call consists of one- to three-syllable barking sounds that are produced during exhalation and which can be transcribed with 'quaha, quaha quaha, quaha quaha quaha' (which is spelled 'quagga' in Afrikaans and, in turn, is said to derive from a Khoisan or Chochoqua name that is the origin of the specific name). The frequency is 10–18 sounds in 5 sec. During inhalation a short 'ee' sound is produced. These calls are individually different and are assumed to serve for individual recognition. A short snort of ca. 1 second in duration is obviously a warning sound, emitted when the animals are disturbed and alerted, such as when discovering a predator or before crossing a river. The long snort of >2 seconds is an expression of well-being (e.g. when feeding).

Although the contact calls of the various equine species sound so different to the human ear, they seem to have some genus-specific properties and are recognized and responded to by congenics. Vocalizations of doubtful communicative significance are: (1) a disyllabic 'ee-ha' (warning?); (2) a high-pitched squeal (pain, distress); and (3) a long squeaking (pain, distress in foals) (Klingel 1967).

Six facial expressions can be distinguished. A greeting expression with a friendly connotation is displayed when two adults establish naso-nasal contacts: necks stretched, ears directed forward, corners of the mouth drawn up in jerking movements and chewing with bared teeth; Kingdon (1979) calls this an 'empty grooming gesture'. The oestrous face is displayed by the oestrous mare when approached and contacted by a stallion: exaggerated chewing movements with open mouth, teeth only partly bared, corners of the mouth pulled up, ears folded back. A submissive gesture, similar to the oestrous face, is displayed by subordinate group members: jaw movements faster than in the oestrous face, teeth meeting each time. The threat expression is displayed in confrontations, and different levels are observed. Low intensity threat: ears slightly directed backwards; high intensity threat: ears straight back, head lowered and stretched forward, swaying sideways, teeth bared. The flehmen expression is a reaction to interesting odours, especially in the sexual context: head lifted up, upper lip curled back to expose the incisors, lower lip lowered but jaws remain closed. When inhaling, odorants are drawn into the nasovomer (Jacobson's) organ, a pocket off the nasal cavity lined with highly sensitive sensory cells. The communicative significance of these expressions is still obscure except for the threat expression, which demonstrates readiness to fight, especially to bite, and conspecifics accordingly move out of the way, flee, or get ready to meet the attack. Other facial expressions with doubtful or no communicative significance are lip clapping (when the zebra see something interesting, like a predator or a human observer) and yawning.

Plains Zebras associate with other herbivores, and particularly with Common Wildebeest. Migrating wildebeest tend to lead the zebra, but because of their slightly faster pace the Plains Zebras eventually get to the front of the mixed herd and tend to lead the way (Klingel 1967). This behaviour, which can be interpreted as an anti-predator strategy, is based on inter-specific social attraction and inter-specific facilitation.

In N Kenya, Plains Zebras and Grévy's Zebras join up and stay together for hours or even days, grazing, resting and fleeing together, but eventually they separate again. When there is only one Grévy's Zebra in the area, a lone territorial stallion, he will stay with the Plains Zebras, and a solitary Plains Zebra stallion will seek company with any Grévy's Zebra, in preference to antelope, but closer contacts are not observed (Klingel 1974, see also Keast 1965). In Namibia where Plains Zebras and Hartmann's Mountain Zebras *E. zebra hartmannae* overlap, members of the two species often meet at waterholes but do not seem to recognize their close relative any more than other visiting ungulates (Klingel 1967, 1968a).

Associations of Plains Zebras and Giraffes *Giraffa camelopardalis* are more accidental, and although frequently cited in the popular literature, there is no hard evidence that zebras benefit from the Giraffes' higher outlook: when Giraffes flee, zebras often stay behind, or vice versa (Klingel 1967, Leuthold 1977). Harmless creatures are sometimes attacked, as was the case when a young Thomson's Gazelle *Eudorcas thomsonii* was killed by a mare who attacked by hitting it with the hooves and biting it (Klingel 1967).

Reproduction and Population Structure According to Smuts (1976c), ♂♂ attain sexual maturity at four years, with adult testis mass reached at five years. In the wild, the youngest family stallions whose ages could be determined when they were immobilized were 5–6 years old, the oldest were over 20. In Ngorongoro, mares have their first oestrus at just over one year of age (13 months; Klingel 1965a), but do not conceive until about 2½ years old. As gestation is 12 months, first foals are born at age 3.5 years (Klingel 1965a, 1969a, 1975). In Kruger N. P., ♀♀ have their first ovulation at about 1.5 years, and by 3.25–5.3 years all have ovulated (Smuts 1976b). Oestrus lasts about six days (Smuts 1976b), whereas Wackernagel (1965) gave a range of 2–9 days for animals in captivity. There is a postpartum oestrus, usually 8–10 days after birth.

Foals are born throughout the year, but not evenly. Distribution is linked to the rainfall pattern. In the Ngorongoro population, 28% (of $n = 151$) were born in the peak month (Jan), and 61% during the main foaling season from Jan to Mar and 85.5% during the six months from Oct to Mar, leaving 14.5% for the remaining six months (Klingel 1969b). Similar patterns of seasonality were recorded in the Plains Zebra populations of Serengeti, Etosha and Hwange National Parks (Klingel 1967, 1969a, 1975, Smuts 1976b). Young weigh about 30–35 kg at birth and there are no records of twins. Weaning takes place at 11 months (sometimes earlier), but lactation can continue up to 16 months; if the mare becomes pregnant, lactation ceases one or two months prior to parturition (Smuts 1976b).

Plains Zebra are prolific breeders. Klingel (1965a) recorded foaling intervals of 378 and 385 days. In the Crater population 15% of the adult mares ($n = 120$) had, in three foaling seasons (1963–65), three foals, i.e. the maximum possible, 33% had two, 41% had one and 10% had none at all; these 120 mares produced 184 foals over three years. These figures are of surviving foals only as neonatal mortality could not be assessed; actual natality was, therefore, even higher (Klingel 1969a). Conception rates of culled zebra in Kruger N. P. were 79% ($n = 236$) and 89% ($n = 31$) (Smuts 1976b); in Loliondo (a subpopulation of the Serengeti), 88% of adult ♀♀ in a shot sample were found to be pregnant (R. O. Skoog pers. comm.). In Ngorongoro, survival rate of the newborn foals was high: only 5% of those recorded disappeared in their first year of life. In the Serengeti population juvenile mortality in the first year was 30% (plus the unknown neonatal mortality) (Klingel 1969a). The different performance of Crater versus Serengeti zebra may have been caused by different predation intensity as the Crater Lion population had been decimated by an outbreak of biting flies *Stomoxys* sp.

Sex ratio at birth is close to 1 : 1 (Klingel 1965a, Klingel & Klingel 1966b, Smuts 1976a). Published adult sex ratios, expressed as ♂♂ : ♀♀, include 0.75 (Smuts 1976a) and 0.69–0.88 (Hack & Rubenstein, in Hack *et al.* 2002), indicating selective predation of stallions (see Grubb 1981). However, published adult sex ratios are likely to be inaccurate as family groups and stallion groups segregate to a certain extent (predation also distorts the sex ratio; see Grubb 1981).

In the wild, longevity is on the order of 21 (Smuts 1976a) to 25 years (Klingel 1966, H. Klingel pers. obs.). One wild-born specimen was about 38 years old when it died in captivity (Weigl 2005; and see Jones 1993).

Predators, Parasites and Diseases Major predators of adult Plains Zebras include Lions and Spotted Hyenas *Crocuta crocuta*, while predators of foals include Spotted Hyenas, African Wild Dogs

Lycaon pictus, Cheetahs *Acinonyx jubatus* and Leopards *Panthera pardus*. The impact of predation and the importance of zebras for predators varies among populations (Kingdon 1979, Grubb 1981). In defence against predators stallions use their teeth and hooves, and they can be quite successful against Lions and Spotted Hyenas. When attacked, the family groups close up and flee, except for the stallion, which attacks the predator and then runs after the group. Mares also attack when their foal has been captured.

Resting predators (Lions, Spotted Hyenas, African Wild Dogs, Cheetahs) are carefully observed, with the zebras arranging themselves in a circle or semi-circle around the predator who has then no chance to hide and/or attack as all the zebra in the vicinity are alerted. Predators on the move are equally well observed. When a predator comes close, but is not heading toward the zebra, they will cross the predator's route at high speed only to stop on the other side, roughly at the same distance from the predator as before. Should the predator change direction and head toward the zebras, they will flee. This feature is observed in other plains ungulate species as well (Klingel 1967, H. Klingel pers. obs.).

Plains Zebra are generally considered to be always fat and healthy and 'you never see a thin zebra'. In fact, they come off condition very fast and can die and/or fall prey within a few days. Healthy Plains Zebras have an impressive parasitic burden: Grubb (1981) summarized what was known of parasites at the time, including up to 11 species of nematodes (including *Setaria* spp., *Strongylus* spp. and *Dictyocaula* spp.), three species of cestodes and several trematodes (including amphistomes and *Schistosoma*). The stomach mucosa is covered with the larvae of botflies (*Gastrophilus* spp.), and another species (*G. haemorrhoidalis*) was recorded from the rectum. The adult fly deposits eggs on the hair, the ensuing larvae are ingested and reach the stomach/rectum where they attach themselves with their mouthparts. None of these parasites seem to cause any ill effects in healthy zebras, but when animals are off condition or when wounded or under nutritional stress, the parasite load gets heavy and especially the increase in numbers of *Strongylus* are likely to contribute to rapid deterioration. Nostril fly larvae *Rhinoestrus* spp. have been recorded from the nasal cavity. External parasites include lice (*Haematopinus*) and ticks (Grubb 1981; and see Horak *et al.* 1984b).

Major diseases of Plains Zebras are anthrax caused by *Bacillus anthracis*, African Horse Sickness caused by a virus and transmitted by biting midges, babesiosis caused by the protozoon *Babesia* (*Piroplasma*) spp., brucellosis caused by the bacterium *Brucella* spp., and trypanosomiasis caused by *Trypanosoma* spp. and transmitted by tsetse flies *Glossina* spp. (see Grubb 1981 and Radcliffe & Osofsky 2002 for references). Plains Zebras in the Serengeti have also tested positive for equine herpesvirus (EHV-9), although there is currently no evidence that it induced mortality. Because of the reported virulence of this virus for more susceptible species such as Thomson's Gazelles, viral transmission from infected zebra to other ungulates may result in mortality (Borchers *et al.* 2005).

Conservation IUCN Category: Least Concern (*E. q. quagga* – Extinct). CITES: Not listed.

As a species, Plains Zebras, numbering close to 700,000, possibly even 1 million, are presently one of the most widespread and abundant of African ungulates. They are present in a number of protected areas across their range, including Serengeti N. P. and Masai Mara N. R. (Kenya/Tanzania), Tsavo N. P. (Kenya), Etosha

Variations in interactions between horizontal limb stripe and vertical body-stripe systems.

N. P. (Namibia) and Kruger N. P. (South Africa). However, some populations are at risk, including the Gorongosa–Marromeu population, which by 1995 had been reduced to a mere 65 individuals from ca. 4000 in 1968 (East 1997, Hack *et al.* 2002). The KwaZulu–Natal populations are vulnerable because of their relatively small numbers (Bowland *et al.* 2001). None the less, the Plains Zebra is a relatively resilient species that has demonstrated a remarkable ability to recover from population declines when provided with suitable habitat and protection from overhunting (Hack *et al.* 2002). Restocking, if necessary, should only be with individuals of the same type and origin, irrespective of the nomenclature, which may be misleading. Also, interbreeding of individuals from different origins as has been practised in South Africa must be strongly discouraged.

Equus zebra MOUNTAIN ZEBRA

Fr. Zebre de montagne; Ger. Bergzebra

Equus zebra Linnaeus, 1758. Syst. Nat., 10th edn, 1: 74. Original type locality given as 'Habitat in India, Africa', since restricted to Perdekop, Ceres Dist., Western Cape Province, South Africa.

Mountain Zebra *Equus zebra*.Lateral, palatal and dorsal views of skull of Mountain Zebra *Equus zebra*.

Taxonomy Two allopatric subspecies of Mountain Zebra have traditionally been recognized, the nominate race *E. z. zebra* (Cape Mountain Zebra) and *E. z. hartmannae* (Hartmann's Mountain Zebra; type locality between Hoanib and Uniab rivers, 19° S, 13° E, Kunene Province, N Namibia). Groves & Ryder (2000) proposed that the two could be treated as distinct species as they are instantly recognizable externally, and Groves & Bell (2004) presented morphological evidence to support separation of the two subspecies as distinct species based on the diagnosability criterion of the phylogenetic species concept. More recently, Moodley & Harley (2005) found no genetic evidence to regard the two Mountain Zebra forms as anything more than different populations; however, the presence of private alleles at nuclear loci rendered the two subspecies genetically distinct evolutionary significant units.

Synonyms: *campestris*, *frederici*, *greatheadi*, *hartmannae*, *indica*, *matschiei*, *montanus*, *penricei*. Chromosome number: $2n = 32$ (Heinichen 1967, 1969a, 1970). There are 13 pairs of meta-submetacentric, one pair of subtelocentric and one pair of acrocentric autosomes; the X and Y chromosomes are both submetacentric. There is little evidence of hybridization between the two subspecies, but this remains a potentially major genetic threat; however, in Damaraland, Namibia, there are reports of hybridization in the wild between Hartmann's Mountain Zebra and donkeys (Brown & Jenkins 1987). Orlando *et al.* (2009) place *E. zebra* closer to *E. africanus* than to any other striped equine.

Description Stocky equid with long, rather thick upright mane, tufted tail and black to deep chocolate brown stripes on a white to light-buffy background. Tip of muzzle is black. Stripes on lower part of face are suffused chestnut to orange coloured.

Mountain Zebras have a distinct dewlap, the function of which is unknown. Rounded ears are white-tipped with black margins and 210–230 mm long (Penzhorn 1988). Stripes on the head are narrowest, followed by those on the neck and body. Horizontal to oblique stripes on the hindquarters are clearly much broader. Narrow dark markings form a 'grid-iron' pattern on the rump. Underparts are white, although the first few stripes behind the forelegs may extend to the ventral mid-line. The legs are distinctly striped to the hooves. One pair of nipples.

Characteristic features of the skull include: occiput high and raised; postorbital constriction deep; orbit somewhat behind the posterior border of the third molar; dorsoventral diameter of orbit greater than in the Plains Zebra *E. quagga*, giving a more rounded orbit; maxillary tuberosity does not extend as far back as in the Plains Zebra, so pterygopalatine fossa is visible from below; external auditory meatus large (3% of the basal length of the skull) and directed horizontally (instead of upward or backward); nasofrontal suture almost straight, and temporal lines diverge more rapidly rostrally than in the Plains Zebra, and at a wider angle (Smuts & Penzhorn 1988, Groves 2002). Canine teeth are prominent in adult ♂♂, while those of the ♀♀ are rudimentary and normally do not cut through the gums (Joubert 1971). In studies of cranial morphology, sexual dimorphism is evident in *E. z. zebra*, where ♂♂ are smaller than ♀♀, while sexes are the same size in *E. z. hartmannae* (Groves & Bell 2004); however, no sexual dimorphism was found in *E. z. zebra* skulls by Smuts & Penzhorn (1988). Age determination, primarily based on incisor wear, has been discussed by Joubert (1972c), Penzhorn (1982d, 1987) and Penzhorn & Grimbeek (1987).

Geographic Variation

- E. z. zebra* (Cape Mountain Zebra): Western Cape and Eastern Cape of South Africa. Smaller in size; dark stripes broader than the light ones.
- E. z. hartmannae* (Hartmann's Mountain Zebra): SW Angola, Namibia and NW South Africa. Larger, with adult ♂ standing about 1.5 m at the shoulder, and tails 0.5 m and ears 280 mm long; dark and light stripes about equal in width, but in some individuals the light stripes are wider than the dark ones; the mane comes further forward between the ears than in the Cape Mountain Zebra; also has relatively narrower muzzle and shorter nasals and diastema (Penzhorn 1988, Groves 2002, Groves & Bell 2004).

Similar Species

Equus quagga. Larger body size; black stripes on heads and bodies wider and fewer; in most extant populations of Plains Zebras in southern Africa the black body stripes continue around the underparts (whereas Mountain Zebras have white underparts, with a central narrow black stripe running from the chest to the belly); no 'grid-iron' pattern on rump, and legs generally not striped to the hooves; presence of shadow stripes in some subspecies (*burchellii*, *crawshaii*); distinct dewlap absent; ears shorter (160–180 mm). S Sudan and S Ethiopia to N Namibia and N South Africa (and historically south of the Orange and Vaal Rivers to the Cape).

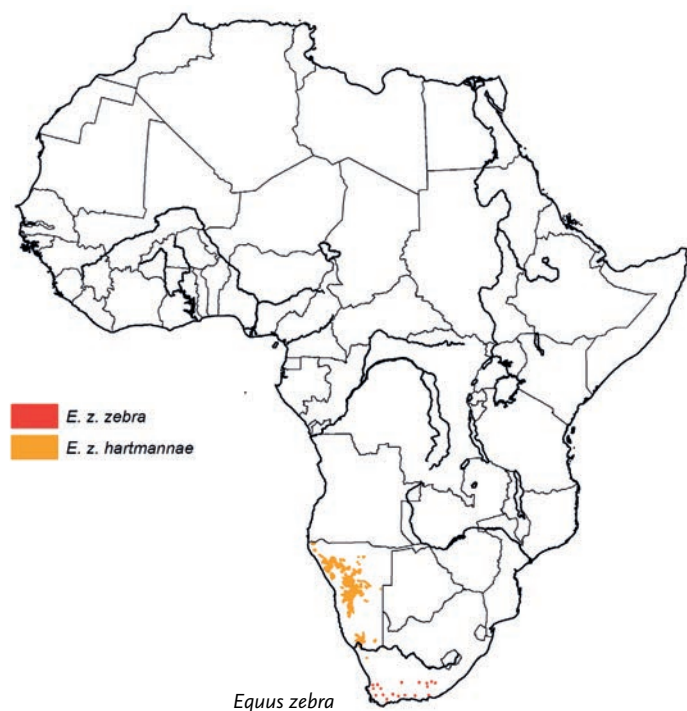

Distribution

Historical Distribution Historically, Mountain Zebras occurred from the southern parts of South Africa through Namibia and into extreme SW Angola. Cape Mountain Zebras were widely, if sparsely, distributed along mountain ranges forming the southern and western edge of the of the central plateau of the Eastern Cape and Western Cape of South Africa, from the Amatola Mts in the Cathcart District westward and northward to the Kamiesberg in Namaqualand in the Northern Cape. Hartmann's Mountain Zebras occur in the mountainous transition

zone between the Namib Desert and the central plateau in Namibia, with a marginal extension into SW Angola. Novellie *et al.* (2002) postulate that the ranges of the two subspecies were separated by an area devoid of mountainous habitat, which occurs between the northernmost point of the Cedarberg and Bokkeveldberg ranges, and the southernmost point of the Kamiesberg range. This large plain, 70 km wide at its narrowest point, which they referred to as the Kamiesberg Gap, may have retarded the flow of genes between the two subspecies.

Current Distribution Today, natural populations of Cape Mountain Zebras occur on the Bankberg (Mountain Zebra N. P.), Gamka Mountain Reserve and the Kamanassie Mts. Populations, mainly from Mountain Zebra N. P., have been re-established in various parts of their historic range, notably Karoo N. P. (Beaufort West), De Hoop N. R., Karoo N. R., now the Camdeboo N. P. (Graaff-Reinet), Commando Drift N. R., Baviaanskloof Wilderness Area, Tsolwana N. R. and Gariep Dam N. R. (Lloyd 2002, Novellie *et al.* 2002).

The present distribution of Hartmann's Mountain Zebras differs from that in historical times, due to the establishment of artificial waterpoints that have allowed it to occupy previously unsuitable habitat. In Angola, a population survived in Iona N. P. (Huntley 1972), though the current status of this population is unknown (Crawford-Cabral & Veríssimo 2005). In Namibia, the subspecies is discontinuously distributed in four populations: from Kunene Province southwards to the Ugab R. and eastwards to the Outjo District; the Erongo Mts; on the escarpment from the Swakop R. southwards to the Naukluft Mts and eastward along the Kuiseb and Gaub drainages into the Khomas Hochland; and the Fish River Canyon and Huns Mts near the Orange R. in the south (Joubert 1973). Hartmann's Mountain Zebras are established in three conservation areas in the Northern Cape, South Africa (Richtersveld and Augrabies National Parks and Goegap Provincial N. R.), and have also been introduced outside of their range in the Western Cape and Eastern Cape (Novellie *et al.* 2002).

Habitat Rugged, broken mountainous and escarpment areas up to around 2000 m with a rich diversity of grass species and perennial water sources. Cape Mountain Zebras in Mountain Zebra N. P. show a regular seasonal movement, from an open grassy plateau in the summer where there are stands of *Themeda triandra* to more wooded hill slopes and ravines in the winter. When the temperature drops sharply, the zebras leave the plateau to seek shelter in the wooded ravines. However, seasonal variations in zebra numbers on the plateau are more closely associated with variations in rainfall than with temperature. The numbers on the plateau are lowest during the driest time of the year (Aug and Sep), rather than the coldest (Jun and Jul) (Penzhorn 1982a, Winkler & Owen-Smith 1995). The movement is associated with a relative change in diet quality (as indicated by crude protein contents of preferred food plants and of the faeces) between the summer and winter habitats. In the summer, faecal and grass protein contents were higher in samples collected on the plateau than in those collected on the hill slopes. In the winter the reverse was the case. On the plateau the cover of grasses in the height range favoured by zebras changed only slightly from summer to winter (Novellie *et al.* 1988).

Mountain Zebras drink daily during the hot, summer months and often do so twice a day, and water is considered an important limiting factor in their distribution (Joubert 1971, Penzhorn 1984a). In spite

of this apparent water dependence, in the Iona N. P. in SW Angola, Hartmann's Mountain Zebras occur on the open sandy plains where they must endure extended periods away from water (Huntley 1972). Where surface water is not available, they will dig for it with a scraping movement of the front hooves, at times excavating to depths of a metre or more.

Abundance By 1998, Cape Mountain Zebras had increased from <100 animals in the 1950s to about 1200 individuals (Lloyd 2002, Novellie *et al.* 2002); the population in 2006 numbered in excess of 1500 individuals (P. Novellie pers. comm.). Hartmann's Mountain Zebras are estimated to number about 25,000 (Novellie *et al.* 2002; and see Conservation).

Adaptations Mountain Zebras are compact, stocky equids and rather resemble donkeys in post-cranial morphology: the scapula and metapodials are short, the ungual phalanges are short on both fore- and hindlimbs, and the metatarsus is shorter than the metacarpus (Groves & Willoughby 1981, Groves 2002). The hooves of Mountain Zebras are compact, with hard ventral surfaces, presumably an adaptation to the type of terrain inhabited (Skinner & Chimimba 2005). Like all equids, the strong, opposing incisors of Mountain Zebras allow them to be coarse grazers. The premolars resemble the high-crowned molars. During cold weather, Mountain Zebras seek shelter in wooded ravines and shallow caves (Penzhorn 1984a). They often graze in the lee of a hill or ridge, protected from the wind. On cold mornings they frequent east-facing slopes to sun themselves (Joubert 1972a).

Foraging and Food Predominantly selective, coarse grazers, only accepting woody plants if forced to do so (Penzhorn 1982, Novellie *et al.* 1988). Mountain Zebras select greener grasses with a high leaf : stalk ratio and little or no moribund material, but use both stem and leaf components. They feed at 40–80 mm above the ground, except when eating seed heads of certain grasses such as *Eragrostis curvula* (and feeding heights range from 310 to 480 mm above the ground). Protein levels of grasses selected generally exceed 5% (Novellie *et al.* 1988). *Themeda triandra* is the favoured grass species in Mountain Zebra N. P., while *Cymbopogon plurinodis*, *Heteropogon contortus*, *Setaria neglecta* and *Enneapogon scoparius* are also eaten. *Digitaria eriantha* is eaten occasionally and *Eragrostis curvula* is used significantly only in winter, when seed heads are eaten (Penzhorn 1982a, Grobler 1983). Certain grasses are uprooted and eaten entirely. There are generally three main grazing periods during the day: a few hours after dawn, late morning, and from mid-afternoon to dusk (Penzhorn 1984a).

Foals will nibble grass when only a few days old (Joubert 1971, Penzhorn 1975). Up to the age of about 14 weeks the foals of both subspecies eat the faeces of adults, particularly that of their own mothers. They paw the faeces and eat parts of two or three pellets, possibly to obtain a supply of the intestinal micro-organisms required to break down cellulose in their food. Mountain Zebras are partial to mineralized soil licks (Penzhorn 1982b).

Social and Reproductive Behaviour Populations consist of small harems of an adult stallion and one to three (maximally five) mares and their dependent foals, and non-breeding groups consisting primarily of bachelors, but sometimes including young fillies (Klingel 1968a, Penzhorn 1984a). The largest breeding herd encountered by

Mountain Zebra *Equus zebra* showing dewlap.

Penzhorn (1975) consisted of 13 individuals, comprising a stallion, five mares and seven foals. The mean number in 21 herds was 4.7 individuals (range 2–13), similar to that given for Hartmann's Mountain Zebras in Namibia (Joubert 1971).

Social hierarchies exist in harems, with the stallion being dominant and a linear hierarchy among the mares. There is no clear-cut association between dominance and leadership, but certain mares tend to initiate most activities in some herds. The stallion usually brings up the rear, except when the group approaches a drinking site in which case the stallion takes the lead. Stallion herd tenure averages seven years (Lloyd & Rasa 1989); one stallion remained with the same harem for >10 years, until he was 17 years old (Penzhorn 1984a). Adult mares typically remain in the same harem for life or until the death or displacement of the stallion. Displacement by younger stallions can lead to serious fighting involving biting and kicking, and stallions can incur severe wounds.

Mountain Zebras are not territorial, but harems inhabit home-ranges, with extensive overlap. Cape Mountain Zebras in Mountain Zebra N. P. had a mean home-range size of 9.4 km² (range 3.1–16.0 km², n = 16). When two breeding herds split up, the home-ranges of the new herds included those of the original herds, but were noticeably larger. Home-range size and shape are probably largely dependent on grazing, permanent water, topography, shelter and lick sites (Penzhorn 1982c). In Hartmann's Mountain Zebra, home-range size varies seasonally: harems have winter home-ranges of 6–10 km² in Daan Viljoen G. R. and 10–20 km² in the Otjovasandu area, Etosha N. P., Namibia; summer home-ranges are considerably smaller at both localities (Joubert 1972a). At Otjovasandu, winter and summer home-ranges are separated by ca. 120 km.

When two harems come into close proximity, the herd stallions approach each other with head erect, and make naso-nasal contact, rub their bodies against each other, sniff at the other's genital area, abruptly resume grazing and move back to their respective herds. Contact between a herd stallion and a bachelor usually consists of brief naso-nasal contact only. The bachelor approaches the herd stallion in a submissive posture (head lowered, grimace, squeal) while

Hartmann's Mountain Zebra *Equus zebra hartmannae* foal.

making chewing motions, possibly grooming-intention movements or a displacement activity derived from nursing behaviour. Fighting, which is rare among Mountain Zebras, consists of biting the opponent's mane, ears, neck or legs, and lashing out with the front or hind legs (Penzhorn 1984a). Playfighting contains all the elements of serious fighting, but the movements are exaggerated.

During its first few weeks of life, the foal remains close to the dam; the dam actively prevents contact between the foal and other members of the group, irrespective of their rank. Suckling intention is signalled to the dam by the foal pressing its body against her chest as it moves around her and attempts suckling on the other side. Weaning seems to depend mainly on the imminent birth of a sibling.

Both colts and fillies leave their maternal harems at about two years of age, slightly younger for the fillies (Penzhorn 1984a, Lloyd & Rasa 1989). Hartmann's Mountain Zebra mares are reported vigorously trying to expel their 14- to 16-month-old foals from the harem before the birth of a sibling. Cape Mountain Zebra foals leave the harem by their own accord; the stallion actively tries herding them back. Birth of a sibling does not appear to be most influential in these foals leaving the harems, as many leave even when no sibling is born. A 37-month-old colt was still with his maternal harem 20 months after the birth of a sibling (Penzhorn 1984a).

Dispersing youngsters tend to join a non-breeding group, colts joining groups with familiar ♂♂ and fillies joining groups with stranger ♂♂. This appears to be a unique incest-avoiding strategy among equids. Fillies joining breeding groups become subordinates in established harems (Rasa & Lloyd 1994). The nuclei of new harems are formed by long-term attachment between colts and fillies within non-breeding groups, the first filly forming such an attachment becoming the dominant mare in the new harem. Generally, colts do not succeed in becoming harem stallions before they are five years old (Penzhorn 1984a).

Vocalizations include a high-pitched alarm call from the stallion when danger threatens and a drawn-out squeal uttered by a bachelor when confronted by a herd stallion. The alarm snort by the herd stallion is actuated by an audible intake of air through the nose, a

Species-specific (signal?) pattern 'gridiron' on rump.

sharp expelling of air, followed by an audible intake. Lipping, a soft sound, audible over short distances near grazing animals, is regarded as a sign of contentment (Joubert 1972, Penzhorn 1984a). It is achieved by forcing air through closed lips, causing them to slap against each other.

Grooming patterns are essentially similar in all equids. Mutual grooming has a utilitarian function as areas that the animal cannot groom itself are groomed by another (especially the neck, mane and shoulders), but it has also attained a secondary function in maintenance of group cohesion. The most frequent mutual grooming in breeding herds is between mares and their foals. This is usually elicited by the foal. Mountain Zebras usually dust-bathe at least once daily, with individual rolling in the sand, first on the one side, then standing up and rolling on the other side.

Mountain Zebras react to flight or alarm signals of large antelope, such as Black Wildebeest *Connochaetes gnou*, but seldom to those of smaller antelope species, with which they seldom associate. Pale-winged Starlings *Onychognathus nabouroup* and rarely Red-winged Starlings *O. morio* and Fork-tailed Drongos *Dicrurus adsimilis* associate with Mountain Zebras, presumably to remove external parasites (and see Predators, Parasites and Diseases).

Reproduction and Population Structure Parturition is aseasonal, although there is a peak in summer. As the gestation period is around 12 months, this also reflects the time of conception (Westlin-Van Aarde *et al.* 1988). In a winter-rainfall area, most foals are born in spring and early summer (Penzhorn & Lloyd 1987); in a semi-arid summer rainfall area, conception occurs later in the season when the spring is dry (Penzhorn 1985). In Mountain Zebra N. P., first conception was recorded at 26 months of age, and mean age at first foaling 66 months (range 38–105 months; $n = 29$); mean foaling interval is about two years (Penzhorn 1985). Gestation is about one year (Joubert 1974b, Penzhorn 1975), and a single foal is born. Hartmann's foals have a mass of about 25 kg ($n = 5$) (Joubert 1974b). Foals have shorter muzzles than the adults, their stripes are less distinct, and they have long woolly hair covering their bodies.

Reproductive success of dominant and subordinate mares is equal and independent of age and social and reproductive variables. However, fitness of dominant mares was significantly higher than that of subordinates, with the latter having higher mortality among foals, part of which could be attributable to dominants' aggression. Dominant mares produce significantly more female than male offspring. This trend is not found for subordinates. A mare's status is positively correlated with dominant status in her female offspring but not related to subsequent status of her male offspring (Lloyd & Rasa 1989).

Sex ratios at birth of Cape Mountain Zebra is usually 1:1 (Lloyd & Rasa 1989). Mortality rates for Cape Mountain Zebra foals at De Hoop was high, with 26% of 42 foals dying. Mortality appears to be related to behavioural factors, as subordinate mares defend their foals vigorously; foals sometimes suffer broken legs probably inflicted by dominant mares (Lloyd & Rasa 1989). Survival rate of Hartmann's Mountain Zebra foals appears higher.

Mares may continue to produce foals up to an age of 21 years and possibly longer, and stallions may remain fertile up to the age of 25 years in the wild (Penzhorn 1985). Jones (1993) gave longevity records for *E. z. hartmannae* in captivity as 26 years and 6 months, and for *E. z. zebra* as 26 years and 3 months, not dissimilar to figures from the wild (Penzhorn 1985, R. Smith pers. comm.). One captive specimen lived for 33.2 years (Weigl 2005).

Predators, Parasites and Diseases In Namibia, Hartmann's Mountain Zebras are subject to predation by Lions *Panthera leo*, Leopards *Panthera pardus*, Cheetahs *Acinonyx jubatus*, Spotted Hyenas *Crocuta crocuta* and African Wild Dogs *Lycaon pictus* (Joubert 1974a). In one instance, it appeared from the spoor and other signs that a stallion had not only kicked an adult Spotted Hyena to death, but had continued to press home its attack over a distance of 100 m, repeatedly kicking the dead hyena (Viljoen, in Skinner & Chimimba 2005). Along the Kuiseb Canyon in the central Namib Desert, significantly more Hartmann's Mountain Zebra mares than stallions are taken by Spotted Hyenas, the only large predators in the area (Tilson *et al.* 1980).

In late winter, Cape Mountain Zebras in Mountain Zebra N. P. carry large tick burdens, especially *Margaropus winthemi* (Penzhorn 1984c, Horak *et al.* 1986). Numerous ixodid tick species have been recorded (Young *et al.* 1973, Horak *et al.* 1984a, 1986, 1992), and between Apr and Nov, Pale-winged Starlings associate with the zebras, and particularly during Jul and Aug. It is thought that the birds exploit a marginal food source during the cold, dry winter months when other food is limited (Penzhorn 1981, Penzhorn & Horak 1989). Various species of bot-flies (*Gasterophilus* spp.) have also been recovered from animals in Mountain Zebra N. P. and Namibia.

Penzhorn (1988) summarizes a lengthy list of nematodes (round worms) recovered from animals across the range (and see Kreczek *et al.* 1994, 1997), as well as at least two tapeworms (*Anaplocephala magna* and *A. perfoliata*), a *Sarcocystis* sp., and the haemoprotozoa *Babesia caballi* and *Theileria equi* that have been reported from Mountain Zebras (Young *et al.* 1973, Markus *et al.* 1983, Penzhorn 1984c, Zweygarth *et al.* 2002).

Epizootics of bovine papillomavirus-induced sarcoid tumours have been reported in several populations in South Africa, including Gariep Dam N. R. (with an incidence of 22% in a population numbering 83 animals) and Bontebok N. P. (53% in 19 animals) and isolated cases in Commando Drif, De Hoop and Gamka Mountain N.

R. (Sasidharan 2006). Available evidence suggests that this predisposition may be a consequence of impaired immune function due to inbreeding (Sasidharan 2006).

Dental abnormalities were found in 7 of 37 skulls collected in Mountain Zebra N. P. (Penzhorn 1984b). Intraventricular thrombosis was found in two Mountain Zebras, while the bacterium *Actinobacillus equuli* was cultured from a three-month-old filly and from various organs of a 20-year-old mare (Bath 1975, 1979).

Conservation IUCN Category: Vulnerable C1 (*E. z. zebra* – Vulnerable D1; *E. z. hartmannae* – Vulnerable C1). CITES: Appendix I (*E. z. zebra*) and Appendix II (*E. z. hartmannae*).

Cape Mountain Zebras were extensively hunted for their skins, because they competed with livestock for grazing, and allegedly because they broke fences (Penzhorn 1988). By the early 1930s it was evident that Cape Mountain Zebras would become extinct if not specially protected, with the subspecies being confined to five localities: mountains west of Cradock, Kouga-Baviaanskloof Mts, Outeniqua Mts, Gamka Mts and the Kammanassie Mts. The Kammanassie, Baviaanskloof and Outeniqua populations occurred on government-owned land at the time and became provincial nature reserves in 1923 (Kammanassie and Baviaanskloof) and 1936 (Outeniqua). In 1937 Mountain Zebra N. P. (1712 ha) was proclaimed in the Cradock District of the Eastern Cape. The zebra population consisted of one mare and five stallions (Pringle 1982). In 1950, when the population had dwindled to two elderly stallions, a neighbouring farmer donated his 11 animals to the park (Bigalke 1952). By 1964 the population had reached 25. In that year a number of adjoining farms were incorporated into Mountain Zebra N. P., increasing the area to 6536 ha and the population to 55 (Penzhorn 1988). Gamka Mountain N. R. was established in 1971; growth of the *E. z. zebra* population in this reserve has been slower than expected, and more intensive management is advocated (Watson *et al.* 2005). Unfortunately, both the Outeniqua and Baviaanskloof populations went extinct, in the early 1970s and 1980s, respectively, perhaps because too many animals were captured to be translocated elsewhere. The remaining three natural populations exist today, while Baviaanskloof has since been restocked.

Today, over 90% of the current total population of 1389 Cape Mountain Zebras in National Parks and Provincial Nature reserves (Lloyd 2002, P. Novellie pers. comm.) are derived from Mountain Zebra N. P. stock. The population in Gamkaberg, which is genetically distinct from the park population, totals around 30–35 animals (Watson *et al.* 2005), while the Kamanassie population totals about 64 (P. Chadwick pers. comm.). All three populations are genetically depauperate. The only population with a relatively high degree of heterozygosity is the one at De Hoop N. R., which derived from Mountain Zebra N. P. and Kamanassie stock (Moodley 2002, Moodley & Harley 2005). The management of the Cape Mountain Zebra metapopulation requires the mixing of at least some animals from the three relict populations, but this has been hampered by the relatively slow growth of the Kamanassie population. Management options to facilitate the growth of this population include changing the fire management in the habitat preferred by zebras, acquiring adjacent land and the translocation of Mountain Zebras onto adjacent land (Chadwick & Watson 2007). Maintaining genetic diversity by establishing new populations is a challenge for the future.

Although vital for the long-term stability of the metapopulation, the De Hoop population received limited monitoring post-1999. Based on a population monitoring programme implemented in 2005, 99 individuals were identified indicating a decline in annual population growth from 6.6% (1995–99) to 4.5% (1999–2005). Furthermore, although population size had increased since 1999, the number of breeding herds had not ($n = 8–10$) and the proportion of adult ♂♂ holding herds of breeding ♀♀ was less than half that in 1999 (17% compared with 38%). The population was male biased (possibly due to the higher mortality rates experienced in ♀♀) and the deficit of ♀♀ is likely to have prevented additional breeding herd formation resulting in excess non-breeding ♂♂. These animals are currently of limited reproductive value to the metapopulation and may be contributing to the decline in reproductive potential at De Hoop by competing for limited resources (Smith *et al.* 2008).

Although most surviving Cape Mountain Zebras are in national parks (793 animals in 2006) or provincial nature reserves (596 in 2006), the numbers on private land have also increased considerably (165; Novellie *et al.* 2002). Some reintroduced populations have performed poorly, such as those in Addo Elephant N. P. and Bontebok N. P. (the latter established in 1985); in total, only 13 of 28 Cape Mountain Zebras reintroductions between 1985 and 1998 were successful (Novellie *et al.* 2002). In those cases where the population increased, the mean number originally introduced was ca. 15. A suitable founder population would be four stallions and ten mares. The average annual rate of increase of the entire Cape Mountain Zebra population from 1985 to 1995 was 8.6% (Novellie *et al.* 1996), and from 1995 to 1998, 9.6% (Novellie *et al.* 2002).

Hartmann's Mountain Zebras occur in four protected areas larger than 1000 km² in Namibia: Skeleton Coast Park, Etosha N. P., Namib-Naukluft Park and Ai-Ais-Hunsberg Park complex. Namib-Naukluft Park, originally established in 1968 as Naukluft Mountain Zebra Park as a refuge for Hartmann's Mountain Zebras, is particularly important, with a population of around 2300 animals (1998 estimate). Around 25% of the national population in Namibia occurs on conservancies

in communal lands with the remainder on commercial livestock and game farms (Novellie *et al.* 2002). In South Africa, an estimated 280 animals occur on private properties and in the Goegap Provincial N. R. in the Northern Cape (numbers in the Richtersveld vary because animals move between South African and Namibia); Hartmann's Mountain Zebras in South Africa's Eastern Cape and Western Cape comprise nearly one-quarter of the population of the subspecies in South Africa, and their removal and replacement with the Cape subspecies is a conservation priority in order to avoid any potential risk of hybridization (Novellie *et al.* 2002).

Measurements

Equus zebra zebra

TL (♂): 2690 mm, $n = 1$

TL (♀♀): 2610 (2550–2690) mm, $n = 5$

T (♂): 420 mm, $n = 1$

T (♀♀): 430 (400–470) mm, $n = 5$

HF c.u. (♂): 510 mm, $n = 1$

HF c.u. (♀♀): 480 (470–490) mm, $n = 5$

E (♂): 220 mm, $n = 1$

E (♀♀): 220 (210–230) mm, $n = 5$

Sh. ht (♂): 1270 mm, $n = 1$

Sh. ht (♀♀): 1240 (1160–1285) mm, $n = 5$

WT (♂): 250–260 kg (est.)

WT (♀♀): 234 (204–257) kg, $n = 5$

South Africa (A. J. Hall-Martin, in Skinner & Chimimba 2005)

Joubert (1971, 1974b) noted that in Hartmann's Mountain Zebra, ♂♂ (mean = 298 kg, $n = 22$) are heavier than ♀♀ (mean = 276 kg, $n = 23$); stallions older than seven years average 343 kg

Family RHINOCEROTIDAE

RHINOCEROSES

Rhinocerotidae Owen, 1845. Odontography: 587. [Previously spelled Rhynocerotidae by J.E. Gray, 1821. London Medical Repository 15: 306.]

| | | |
|----------------------------------|------------------|--------|
| <i>Ceratotherium</i> (1 species) | White Rhinoceros | p. 445 |
| <i>Diceros</i> (1 species) | Black Rhinoceros | p. 455 |

Rhinoceroses were, until recently, among the largest land mammals inhabiting African landscapes. True rhinoceroses, of the family Rhinocerotidae, together with the extinct Amarynodontidae and Hyracodontidae, constitute the superfamily Rhinocerotidae, the largest and ecologically most diverse group of Perissodactyla (Prothero *et al.* 1989). The rhinocerotoids were distributed widely across Eurasia, North America and Africa, and by far outnumber all other perissodactyl groups in terms of valid fossil genera (>50) and species (several hundreds). While the amynodonts and hyracodonts were reduced to a few genera by the early Oligocene, the Rhinocerotidae began to diversify and to dominate the fauna of the northern hemisphere and Africa during the Miocene. The rhinos of North America were extinct by the end of the Miocene, while those of Europe and the northern parts of Asia survived to the end of the Pleistocene. As remnants of this diverse group, the genera *Rhinoceros* (represented by two species) and *Dicerorhinus* (one species) are precariously still extant in Asia, and the monotypic genera *Ceratotherium* and *Diceros* currently survive in Africa.

All recent species have been allocated to the subfamily Rhinocerotinae, and the African species form the tribe Dicerotini and the Asian species the tribe Rhinocerotini. However, there are a number of different views on the phylogenetic relationships of the extant rhinos; for instance, in a classification proposed by Antoine (2002) all five extant species have been combined in tribe Rhinocerotini and subtribe Rhinocerotina, while Prothero *et al.* (1986) and Cerdano (1995) separated the two recent African genera into the subtribe Dicerotina.

According to Tougaard *et al.* (2001), the origin and evolution of African rhinos occurred in the middle Eocene, with the *Diceros*/*Ceratotherium* split dated to 17.1 ± 2.5 mya (middle Miocene). It has been suggested by Geraads (2005) that the Pliocene *Ceratotherium neumayri* was a likely ancestor for both living African species, because it was morphologically and ecologically intermediate between them. The two lineages leading to the recent species split soon after the Miocene–Pliocene boundary leading from an ancestral mixed feeder (*C. neumayri*) to a lineage of grazers (*Ceratotherium* species) and one of browsers (*Diceros*). *Ceratotherium* adapted to open grasslands and savannas, while the *Diceros* ecological niche consisted of more closed habitats (Geraads 2005).

The genera *Diceros* and *Ceratotherium* are morphologically defined by synapomorphies that include the loss of both upper and lower incisors, an astragalus facet that is more or less flattened, an occipital crest angle above 100°, an inclined orbital floor, strong supraorbital processes, and short rounded nasals (Groves 1983, Cerdano 1995, Tougaard *et al.* 2001, D. Geraads pers. comm.). *Diceros* has three molars and 3–4 premolars (total 24–28 teeth), while *Ceratotherium* always has three molars and three premolars (total 24).

Rhinoceroses are large-bodied, pachydermatous animals, endowed with one or two nasal horns consisting of aggregations of keratin fibres (Cave 1969). The skin consists of a heavily keratinized and pigmented

epidermis (about 1 mm thick) and a dense dermis (about 18–20 mm thick) composed of pure collagen fibres (Cave & Allbrook 1959). A covering of very sparse hairs is found in some individuals, especially when young (Neuville 1927). The White Rhinoceros *Ceratotherium simum* exceeds all other extant rhino species in size, with a body length reaching 4.2 m, a shoulder-height up to 1.9 m and weight of 3600 kg in adult ♂♂, compared with 3.75 m, 1.8 m and 1500 kg, respectively, in the Black Rhinoceros *Diceros bicornis* (Zecchini 1998). African rhinos do not show conspicuous folds in the skin characteristic of *Rhinoceros* species.

The cytogenetics of the family have been investigated by several authors. The modal diploid chromosome number for all species is 2n = 82 (the ancestral condition), with the exception of *Diceros* (2n = 84) and the Javan Rhino *Rhinoceros sondaicus*, where the karyotype is unknown; the X chromosome in *Ceratotherium* and *Diceros* is identical (Houck *et al.* 1995).

Rhinoceroses always have one young, after a gestation period of about 480 days in all species (Rookmaaker 1998a). Placentas are large and consist of a thin membrane of allantochorion with rather diffusely scattered villi (Benirschke & Lowenstine 1995). In the wild, rhinos were originally found in a large variety of habitats, probably only avoiding very dense forests. They are generally solitary, but *Ceratotherium* sometimes congregated in groups, aggregations that were much rarer in *Diceros*. They are sedentary and territorial, and consume a wide variety of available plant species shifting preferences according to circumstances. They have few natural enemies, and there are few instances in which predators attack young rhinos.

Rhinoceroses were shown a dozen times in the arenas and menageries of the Roman empire, and some of these must have been caught in Africa (Störk 1977). In Renaissance Europe, most descriptions of the animal in the bestiaries of the period were based on the image of a single-horned animal, probably from India, seen in Lisbon in 1515 (and notably copied in a woodcut by Albrecht Dürer) (Clarke 1986). African rhinoceroses were first observed by European adventurers from about 1650 when the interior of the Cape of Good Hope began to be explored. For at least a century, however, reports were equivocal about the number of horns, and Linnaeus (1758) still called it an obscure species (Rookmaaker 1998b). Rookmaaker (2005a) has pointed out that the distinctions between rhinos from Asia and those of Africa only became formalized at the end of the eighteenth century.

In the course of the nineteenth century adventurers and hunters travelling inland from the South African coast described a proliferating number of rhinoceros species, mainly because they thought that the sizes and shapes of horns were significant characteristics. Two kinds of Black Rhino and two kinds of White Rhino came to be recognized in the southern part of Africa, but when still more types were added the picture became so confused that a prolonged nomenclatural silence followed while a revision was awaited (Rookmaaker 2005b). The first captive Black Rhino arrived in Europe in 1868, while the White Rhino was first seen in a zoological garden as late as 1946 (Rookmaaker 1998a). The studbooks of African rhinos in captivity are kept by the

Zoological Gardens in Berlin and contain data on all specimens around the world (Ochs & Mercado 2005a, b, Rookmaaker 2005c).

The rhinoceros has limited value in traditional African societies. In a few cases, the hide was used to prepare shields or the meat was eaten (Lagercrantz 1960). The major threat to rhinos in recent years stems from the immense value of the horns to the Chinese as an essential ingredient in traditional fever-reducing medicine (Martin & Martin 1982, Chapman 1999, Ellis 2005) and to Yemeni to produce handles of the

daggers worn by the men (Leader-Williams 1992, Martin & Vigne 1993). The conservation of the species is discussed in further detail elsewhere.

References to an extensive literature about all aspects of rhinoceros biology and conservation have been listed and discussed by Rookmaaker (1983), Wildi (1989), Miller (1992), Du Toit *et al.* (1994) and Van der Westhuizen (1994).

Ceratotherium, principal mass of skull in relation to mastication, horns, vertebral column and suspension.

GENUS *Ceratotherium* White Rhinoceros

Ceratotherium J. E. Gray, 1868. Proc. Zool. Soc. Lond. 1867: 1006, 1027.

Ceratotherium is a monotypic genus (but see Groves *et al.* 2010), represented by a single extant species, the White Rhinoceros *Ceratotherium simum*. This species once was found in Africa south of the Zambezi R. and further north in central Africa in parts of Uganda, DR Congo, Sudan, Central African Republic and Chad (Heller 1913, Groves 1972, 1975). The unbridged gap between the two populations merits further investigation. The White Rhino was exterminated in Zimbabwe in 1893, at which time only a small population of a minimum of 20, but most likely about 200, individuals remained in the south-eastern part of South Africa (Player 1972, Rookmaaker 2002, 2003b).

The earliest African representative of *Ceratotherium* in the Pliocene is known from Langebaanweg in South Africa and has recently been identified as *Ceratotherium mauritanicum* (Geraads 2005). In North Africa, *C. mauritanicum* survived into the late Pleistocene; *Ceratotherium simum* was first found in the early Pleistocene. Specimens found in East Africa have been described as *Ceratotherium simum germanoaffricanum* (see Groves 1975). Evidence of skeletal material suggests that the transition from *C. mauritanicum* to *C. simum* took place in East Africa (Geraads 2005). Fossil and extant members of the genus are typical grazers, which shows in the elongation of the occiput and the development of the nuchal hump to accommodate the muscles needed to lift the head from the grazing posture (Alexander & Player 1965).

White Rhinoceros *Ceratotherium simum*: skeleton (top) and myology (bottom).

***Ceratotherium simum* WHITE RHINOCEROS (GRASS RHINOCEROS, SQUARE-LIPPED RHINOCEROS)**

Fr. Rhinoceros blanc; Ger. Breitmaul-Nashorn

Ceratotherium simum (Burchell, 1817). Bull. Sci. Soc. Philom. Paris: 96–97, pl., figs. 1, 2. 'L'interior de L'Afrique Méridionale vers le vingt-sixième degré de latitude'; since fixed as South Africa, North-West Prov., Chue Spring (= Heuningveli), about 26° 15' S, 23° 10' E; see Grubb 1999).

White Rhinoceros *Ceratotherium simum*.

Taxonomy First described by Burchell from a specimen collected 150 km north of Kuruman in what is now the North West Province in 1812 (Burchell gave the type locality as 'Interior of South Africa near 26° S'). He applied the name *Rhinoceros simus*, the genus *Ceratotherium* being proposed by Gray in 1867. Two subspecies are recognized: *C. s. simum* in southern Africa, and *C. s. cottoni* in north-east Africa. The nucleotide sequence divergence between them is only 1.4% (George *et al.* 1993). Groves *et al.* (2010) recognized *C. s. cottoni* as a distinct species. Synonyms: *burchellii*, *camperis*, *camptoceros*, *camus*, *cottoni*, *crossii*, *kiaboaba*, *kulamane*, *kulamanae*, *oswellii*, *prostheceros*. Chromosome number: $2n = 82$, and there is no diagnostic karyotypic difference between the two subspecies (Heinichen 1967, 1969b, Houck *et al.* 1994, 1995); the X chromosome is a large submetacentric, the Y is a small submetacentric, and the autosomes are telocentric and acrocentric (Houck *et al.* 1995). Chromosomal polymorphism, resulting in three individuals with a diploid number of $2n = 81$, has been noted in the Northern White Rhinoceros (Houck *et al.* 1994). Robinson *et al.* (2005) recently confirmed a case of inter-specific hybridization in rhinoceroses, wherein a calf was born to a young White Rhino cow and a Black Rhino bull held in captivity; the hybrid showed a mixture of phenotypic traits characteristic of the two species.

Description Largest extant rhinoceros species, but closely rivalled by the Indian Rhinoceros *Rhinoceros unicornis*. Skull is lengthened and lips broadly squared, with a hump on the neck containing the ligament and associated muscles supporting the massive head. Pointed ears fringed with hair, but otherwise body hairs are sparse and detectable only on close examination. Body is barrel-shaped due to the extended rib cage, with a prominent vertebral crest in the dorsal region and, particularly in the southern subspecies, rib-like markings on the trunk

White Rhinoceros *Ceratotherium simum* detail of open mouth.

There are several theories to explain the origin of the name 'white rhino', the most popular explanation being that 'white' is derived from the Afrikaans 'wyd' or Dutch 'wijd' (meaning wide). However, there is no basis for this conjecture, since earliest reports consistently refer to the 'white rhinoceros' or 'witte renoster' (see Rookmaaker 2003a, Feely 2007). The name 'white rhino' may derive from the pale colour of the first specimens encountered where calcareous soils predominate. The more accurately descriptive names 'Square-lipped Rhinoceros' and 'Grass Rhinoceros' have been coined quite recently.

ABOVE LEFT: Lateral, palatal and dorsal views of skull of White Rhinoceros *Ceratotherium simum*.

ABOVE RIGHT: White Rhinoceros *Ceratotherium simum* lips and musculature adapted to grazing.

of the body. There are prominent folds of skin near the top of the forelimbs, and in the flank where the upper part of each hindlimb joins the body. Skin colour is battleship grey, but is modified by the colour of the soil used for wallowing. Limbs are thick-set, with three toes bearing broad, stout nails on each foot. Tail short with a sparse fringe of bristly hairs. Females bear a pair of inguinal nipples. Males lack a scrotum, and the muscular penis points backwards when enclosed in its sheath. Preputial glands are present. Apart from genitalia there is little sexual dimorphism, except that ♂♂ attain a body mass about one-third larger than ♀♀ and have noticeably more heavily set heads, chests and necks.

Two keratinous horns lacking a bony core grow in tandem on the snout, the anterior longer than the posterior. The horns are made up of a mass of tubular filaments similar in substance to hair, and are actually outgrowths of the skin not attached to the bone of the skull. Front horn has a straighter transverse edge in front when compared with that of the Black Rhino. Male horns have a greater mean anterior basal circumference than female horns, while ♀♀ generally bear more slender, and sometimes longer, anterior horns than ♂♂. Adult ♂♂ have heavier horns than ♀♀. Mean mass of horns of adult White Rhinos was 5.2 kg ($n = 163$) for anterior horn and 1.9 kg ($n = 153$) for posterior horn (Pienaar *et al.* 1991, Pienaar 1993). No difference between adult sexes in intrinsic anterior horn growth (mean rate of 50 mm per year; range 25–66); intrinsic horn growth rate is rapid in young animals, about 150 mm in the first year of life, but growth rate of anterior horns decreases with age (Pienaar *et al.* 1991, Pienaar 1993; see Horn Measurements).

Skull elongated, occipital crest rising high at the rear of the skull, with a broad rugose area on top of the skull providing a broad area for attachment of the neck muscles. Zygomatic arches heavily built and provide firm attachment for masseter muscles that operate the lower jaw. Lower jaw massive, condyles very broad and fitting into deep sockets. Adult dental formula is $I^{0/0}, C^{0/0}, P^{3/3}, M^{3/3} = 24$. Four premolars in deciduous dentition; no incisors or canines in deciduous dentition, which are sometimes present in Black Rhinos. Upper and lower second molars are the largest of the cheekteeth (Skinner & Chimimba 2005). Patterns of tooth eruption are discussed by Hillman Smith *et al.* (1986).

Geographic Variation

- C. s. simum*: Southern White Rhinoceros; southern Africa only, though introduced to Kenya, Uganda (where the species, but not subspecies, formerly occurred) and Zambia.
- C. s. cottoni*: Northern White Rhinoceros; formerly in Central African Republic, Chad, Sudan, Uganda and NE DR Congo; now probably extinct in the wild. Dorsal outline of the skull less concave than in the southern subspecies, a shorter tooththrow length, slightly longer legs relative to body length (Heller 1913), slightly smaller size overall (see Measurements), and generally higher head carriage.

Similar Species

Diceros bicornis. Sympatric, over various parts of the range of the southern subspecies. Considerably smaller, with hooked upper lips; skull shorter and broader, with occipital part not produced backwards behind condyles; head generally held high; more rounded ears with ear tips pointing upwards; and concavely saddled outline to the back.

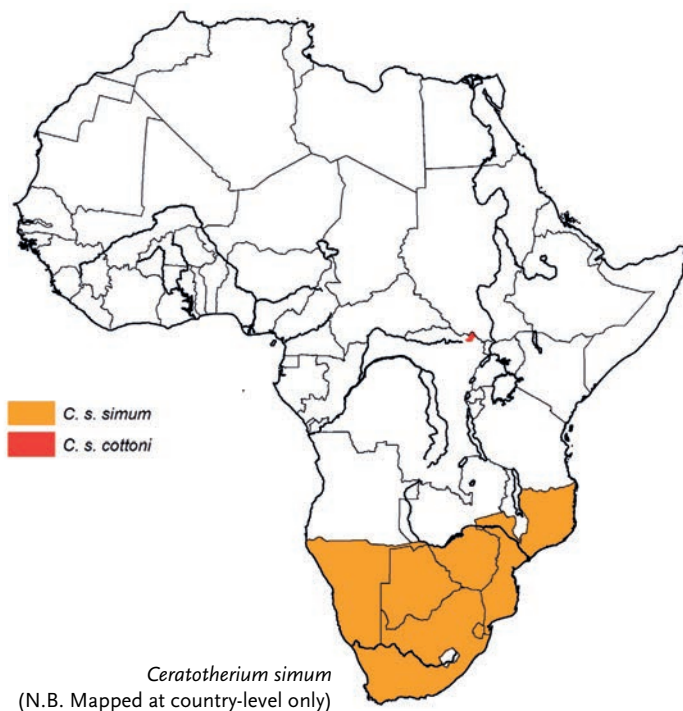

Distribution

Historical Distribution The southern subspecies formerly occurred from the Zambezi R. southwards into South Africa, in the east as far as NE KwaZulu–Natal, and in the west through the Northern Cape north of the Orange R. into NE Namibia. That they ever occurred naturally in Zambia is not definitely known; Ansell (1978) notes they may have occurred between the Zambezi and Mashi Rivers in the south-west of the Western Province, but considers the Zambezi R. as the northern boundary of the southern subspecies. White Rhinos were particularly abundant in the North West Province of South Africa, E Botswana and SW Zimbabwe. The species was absent from the highveld region of interior South Africa. Through hunting the species was almost exterminated, except for a remnant of a few score animals that persisted near the Umfolozi R. in the extreme south-east of the range. This core population has recovered such that White Rhinos have been re-introduced into many parts of their former distribution in southern Africa, and even to parks in East Africa outside the historic distribution range (see also Conservation).

The northern subspecies was found historically to the west of the upper Nile R., from NW Uganda and NE DR Congo northwards into S Sudan and into adjoining parts of the Central African Republic and southern edge of Chad. A feature of the historic distribution of the species as a whole is the limitation by major rivers, presumably because of a limited swimming capability.

White Rhinos formerly occurred through much of East Africa, as is attested by abundant fossil remains in early to mid-Pleistocene deposits in places like Olduvai Gorge. Teeth found on the soil surface in Kenya, and rock paintings in Tanzania, suggest that the species persisted in East Africa until a few thousand years ago (Hooijer & Patterson 1972). Rock engravings in Algeria indicate that the distribution range extended into North Africa in the early Holocene.

Current Distribution South Africa remains the stronghold for this subspecies, with sizeable populations in Kruger N. P. and Hluhluwe–

Umfolozi, but also occurring in numerous protected areas and private reserves throughout the country. There are also smaller re-introduced populations within the historical range of the species in Namibia, Botswana, Zimbabwe, Swaziland and Mozambique (Emslie *et al.* 2007). Populations have also been introduced outside of the former range of the subspecies to Kenya, Uganda and to Zambia. A population introduced to Côte d'Ivoire is considered semi-captive (Emslie & Brooks 1999, 2002a).

The northern subspecies is now extinct in Uganda, Chad, Central African Republic and at least up until 2006 survived in the wild only as a tiny remnant in Garamba N. P. in DR Congo (Emslie & Brooks 1999, Hillman Smith 2001, Emslie *et al.* 2007). The subspecies is now probably extinct in the wild (Milliken *et al.* 2009, Emslie 2011). Reports of rhinos surviving in S Sudan are unconfirmed; none were reported during the survey by Fay *et al.* (2007).

Habitat In southern Africa White Rhinos are typically associated with drier forms of savanna woodland, with mean annual rainfall under 750 mm. In Hluhluwe–iMfolozi Park they favour thornveld dominated by *Acacia* spp., but in Kruger N. P. they have settled abundantly in broadleaf savanna on granitic soils where *Combretum* spp. predominate (Pienaar *et al.* 1993a). Selous (1899) reports that they were partial to broad grassy valleys within savanna woodland regions of Zimbabwe. They were not recorded historically in treeless grasslands of the Highveld and interior KwaZulu–Natal. Being water-dependent, White Rhinos are seldom found further than about 5 km from surface water.

Heller (1913) described the habitat of the northern subspecies in Sudan as an open savanna containing scattered *Combretum* trees, and tall grass over 2 m in height during the wet season. The recent range in Garamba N. P. is likewise mostly tall *Loudetia/Hyparrhenia* grassland on lateritic and granite-derived sandy soils with widely scattered trees of *Vitex doniana* and *Terminalia mollis*. Falling within the Sudano-Guinean Savanna belt, the natural state of this area is tree/bush savanna or *Combretum/Terminalia* woodland, but the southern part of Garamba, where the rhinos are protected, is maintained as more open grassland by frequent intense fires and high elephant density. The area is regularly dissected by flowing rivers with patches of gallery forest. Rainfall from 1980 to 1988 averaged 1265 mm per year, though from 1957 to 1963 the average had been 1627 mm (Hillman Smith 1989). A crucial feature of this habitat is the presence of regularly spaced termitaria clearings. They cover 10–12% of the surface area of the grassland, but an average of 42% of all rhino observations over a ten-year period were in termitaria clearings. The *Loudetia* grass is unavailable to the rhinos as a food source above 0.5 m in height, but in the long grass seasons the termitaria clearings are the site of smaller, more palatable species. The long grass areas are used by the rhinos for cover, both for resting during the day and when disturbed, but it is the termitaria within the long grass that provide the combination of protection and airflow (K. Hillman Smith pers. comm.).

Abundance The Southern White Rhino is the most numerous of all rhino taxa, and its recovery from just a few score individuals has been recognized as among the world's greatest conservation success stories. As of 31 December 2010, there were an estimated 20,160 animals surviving in the wild, the majority of which (18,796) were in South Africa. Namibia (469), Kenya (365) and Zimbabwe (290) are the only other countries with over 250 wild Southern White Rhino, and together they conserve 82% of the subspecies outside of

South Africa. Smaller populations exist in Botswana (135), Swaziland (88), Uganda (9), Zambia (7) and Mozambique (6) (Emslie 2011).

In iMfolozi, Southern White Rhinos had attained local densities exceeding 5/km², and a regional density of 3/km², at the time of Owen-Smith's study in 1970 (Owen-Smith 1973). The species constituted about half of the total biomass of large mammalian herbivores. Numbers have subsequently been held below this level through regular live removals. The former high abundance of the species in favourable habitat is attested by reports from early explorers of up to 80 animals being seen during a day's journey with wagons through the Magaliesberg region of South Africa's North West Province (Harris 1838). In Kruger N. P., the growing White Rhino population has attained local densities of 0.5–1.4 animals/km² (Pienaar *et al.* 1993b).

The northern subspecies was locally, rather than generally, abundant (Roosevelt 1910), but several thousand must have occurred in five countries at the start of the twentieth century. In 1960, the population was estimated to have stood at about 2230 individuals (Emslie & Brooks 1999). Four animals were last seen in Garamba N. P. in the Democratic Republic of Congo in 2006 and only spoor found in 2007. Since then there have been no signs of rhino despite intensive ground-based searches, except for a 2–3-year-old poached carcass found in 2008, and it is now believed this population is extinct (Milliken *et al.* 2009, Emslie 2011).

Adaptations The most notable adaptations are those facilitating a grass diet, in particular the lengthened head, widened lips, absence of incisor and canine teeth in both jaws, and high-crowned premolars and molars, possessing convoluted enamel layers on their biting surfaces adapted to grinding up coarse food. The skin is extraordinarily dense, tough and inelastic, varying in thickness from 18 to 24 mm, although the epidermal layer is only 1 mm deep. Large apocrine sweat glands, with myoepithelial cells arranged round the ducts, are distributed over the body. Following extreme exertion, White Rhinos may suddenly become covered in sweat over the whole head and trunk region. Wallowing in pools of water or in mud aids in thermoregulation, although wallowing is not restricted to the mid-day period. The ears may play an additional role in heat loss, being moved around restlessly even when animals are apparently sleeping. The body temperature is fairly low (34–37°C), and may vary over a 3–5°C range during the course of the day (Allbrook *et al.* 1958, Wallach 1969). During mid-day, they congregate in shady rest-places usually situated on ridge-crests. Here they may slumber for up to 8 h during mid-summer, but the rest period is reduced during the cooler winter period. During cold, windy weather animals seek shelter in dense woodland patches. A subcutaneous layer of fat up to 50 mm in thickness may build up on the abdomen, providing a buffer against malnutrition during the dry season.

The nasal sinuses take up almost as much space in the skull as the brain, indicating strong dependency on olfaction. White Rhinos may respond to human scent at ranges as great as 800 m, and can follow the tracks of other rhinos over an hour later. Animals of the southern subspecies walk with head held low and nostrils close to the ground, such that in sandy soil the mouth may make a sinuous track, but the northern subspecies holds the head higher, probably because of the longer grass habitat. Hearing is sharp, but vision poor. Animals react to a person walking past in clear view at ranges of 80 m, but with some uncertainty. However, they appear unable to identify a motionless human observer at ranges greater than 15–20 m.

White Rhinoceros *Ceratotherium simum* grazing and head lift diagram.

The White Rhino is a hindgut fermenter with a capacious large intestine where digestion of plant fibre occurs. The mean retention time of dye-marked food particles in the digestive tract was around 60 h (Foose 1982). As a result of the prolonged retention about 50% of cell wall components of a standard grass hay may be degraded, a digestive efficiency lower than that of grazing ruminants but better than equids. Grass is cropped by grasping material between the upper lip and a pad on the lower lip, then breaking it off by inward movement of the lips or slight jerk of the head. The width of the bite is around 20 cm, the biting rate as much as 80/min, and height of cropping down to as low as 10 mm above ground level (Owen-Smith 1973, Shrader 2003). This enables these large animals to obtain an adequate rate of intake even from short grass swards. Defecation takes place 4–6 times per 24 h, and the boluses contain much coarse grass material.

White Rhinos drink daily during the wet season when water is abundant. During the late dry season when animals must travel perhaps several kilometres to water, they may drink only every 3–4 days. Drinking generally takes place during the late afternoon or early evening through to midnight, so that travelling to and from water occurs during the cooler hours. After wallowing in mud, animals rub various parts of the body against convenient trees, rocks or termite mounds, which become quite highly polished. This action may serve to remove ticks along with the mud. The mud coat may also serve some protection against biting flies.

Despite their large size, White Rhinos move quite gracefully with marked flexure of the carpal joints. The walking speed is 3.0–3.8 km/h. Animals generally trot with a high-stepping action while hastening from a human intruder, and can maintain this gait for several kilometres at a speed of 29 km/h. Galloping takes place only over short distances except by small calves, and the top speed is reported to be 40 km/h. In a study of locomotion and bone strength in the White Rhino, Alexander & Pond (1992) found that the stresses developed in the long bones in running are rather low, in comparison with other large mammals, suggesting that rhinoceros skeletons may be built to unusually high factors of safety.

Foraging and Food Strictly a grazer, with forbs normally constituting no more than about 1% of the diet. Occasional instances reported of White Rhinos chewing on woody stems, otherwise no browsing observed. In Hluhluwe–iMfolozi Park, they favour short grass areas where species of *Panicum*, *Urochloa*, *Digitaria*, *Sporobolus* and *Cynodon* predominate. Such species can constitute over 50% of the diet during the wet season. Since some of these grass species grow in a tufted form elsewhere, a prostrate growth form appears to be cultivated by the grazing pressure of White Rhinos. Much foraging occurs around termite mounds, sites of former human habitation and other areas where nutritious short grasses prevail. During the dry season White Rhino transfer their grazing more towards taller tuft-forming grass species, especially *Panicum maximum* growing

under tree canopies and *Themeda triandra* in more open areas. The latter species can constitute up to half of the diet at this time of the year. Under extreme conditions they may extend their foraging up hillsides where tall grass reserves remain. Apart from lawn-forming species like *Cynodon dactylon* and *Dactyloctenium australe* growing under shade canopies, fibrous grasses growing in sandy soil areas are eaten little. Aromatic grasses like *Cymbopogon* spp. are rejected, although *Bothriochloa* is eaten when short. The grazing impact of White Rhinos promotes the formation of a mosaic interspersed of short and tall grasslands (Owen-Smith 1988, Waldram *et al.* 2007).

White Rhinos of the northern subspecies have been observed feeding on medium-tall grasses of the genera *Hyparrhenia*, *Panicum*, *Chloris*, *Heteropogon* and *Brachiaria* (Foster 1967, Van Gysegheem 1984). In Garamba N. P., *Loudetia arundinacea* was only grazed by White Rhinos when the grass was below 0.5 m in height. Recent park management promoted mosaics of short grass for feeding and long grass for cover, but the remaining rhinos were not at sufficiently high density to maintain lawns themselves. In the later wet season, their feeding was largely restricted to medium-tall grasses of the genera *Brachiaria*, *Pennisetum*, *Sporobolus*, *Cynodon*, bordering termitaria or occurring sparsely elsewhere, certain forbs growing on termitaria, and *Eleusine* along rivers.

White Rhinos are typically active for about 50% of the 24-h cycle, distributed equally between day and night, with most of this time spent foraging. Peak grazing activity occurs during the early morning and late afternoon, extending into the night. However, when food is plentiful daytime foraging activity is reduced. Foraging time tends to decline during the dry season, perhaps to conserve energy when only poor-quality grass is available. Greatest daytime activity occurs during the period of new grass growth at the start of the early wet season, and frequent wallowing indicates that animals are under much thermal stress at this time of the year when their feeding time extends towards the hot mid-day period.

Social and Reproductive Behaviour Social organization is structured around the territorial system of adult ♂♂. Territories are occupied year-round by a dominant adult ♂, and perhaps shared with one or more subordinate adult ♂♂. They encompass 0.8–2.6 km² in high-density regions of Hluhluwe–iMfolozi Park (Owen-Smith 1975) and 2.6–9.0 km² elsewhere in this park (White *et al.* 2007), and are also larger in less favourable habitat: 2.5–13.9 km² in Ndumo G. R. in KwaZulu–Natal (Conway & Goodman 1989), 1.7–3.7 km² in Kruger N. P. (Pienaar *et al.* 1993b), 1.4–5.0 km² at Matobos in SW Zimbabwe (Rachlow *et al.* 1999), and 5–11 km² in SE Zimbabwe (Condy 1973). However, territories as large as 50–100 km² to more than 100 km² have been documented for low-density populations elsewhere (Roche 2000, P. Kretschmar pers. comm.).

Female home-ranges extend over 10–20 km² in Hluhluwe–iMfolozi Park, including a favoured core encompassing 5–10 km² where each ♀ spent most of her time while food and water remained abundant, but some individuals may move over much larger ranges (Owen-Smith 1975, White *et al.* 2007). Home-ranges of 40–50 km² are reported from elsewhere in southern Africa (Pienaar *et al.* 1993b, Rachlow *et al.* 1999). White Rhinos of the northern subspecies introduced into the E Nile region of N Uganda moved over annual ranges approaching 100 km² (Van Gysegheem 1984). In Garamba N. P., where the population is at very low density, adult ♂♂ ranged over areas of 125–

230 km², while ♀ home-ranges covered 200–500 km² (K. Hillman Smith pers. comm.). Both total home-ranges as well as the core areas of ♀♀ generally overlap extensively. Female home-ranges also encompass several female territories (Owen-Smith 1975, Pienaar *et al.* 1993b, White *et al.* 2007). Adult ♀♀ may temporarily abandon their home-ranges during adverse conditions, but return to them thereafter, although some individuals may shift home-ranges over their life-span (Owen-Smith 1973). In Garamba N. P., shifts in the home-range of a ♀ were sometimes associated with the birth of a new calf. Animals peripheral to a ♀ and her current calf tend mainly to be the older offspring of that individual (K. Hillman Smith pers. comm.).

Adult ♂♂ older than 10–12 years are basically solitary, but territory holders were temporarily associated with a ♀ and her companions on about 40% of occasions seen (more in the wet season, less in the dry season). Subordinate adult ♂♂ are likewise usually found alone, and associate only briefly with ♀♀. Adult ♀♀ are most commonly found in dyads consisting of a mother and her offspring, or a ♀ accompanied by a subadult that is generally not her progeny (Owen-Smith 1975). However, in Garamba N. P., 50% of female calves remained with or re-joined the mother and her next offspring (K. Hillman Smith pers. comm.). Occasionally, two adult ♀♀, both lacking an offspring, may join together for a period, and sometimes a young subadult attaches itself to a cow–calf pair to form a triad. Larger social groups may be formed where several subadults join up with a ♀ lacking a small calf, the largest such unit including eight individuals. Subadults most commonly form same- or mixed-sex pairs, triads or larger groups. Temporary associations numbering up to 16 individuals can be observed, usually with an adult ♀ as the core, especially where animals congregate around resting areas or waterpoints. Bonds between individual subadults can endure for several years. Subadult ♂♂ persistently form attachments until about ten years of age. Young ♀♀ separate from subadult companions following the birth of their first calf around seven years of age (Owen-Smith 1988).

Territory holders confine their movements year-round to within their own territories, except for excursions to seek water for drinking during the dry season. Territories are marked through spray-urination concentrated along boundaries, and dung scattering performed at large hollowed-out dung heaps at borders. Territory holders also add their contributions to the middens formed where other rhinos have defecated. Subordinate ♂♂ restrict their movements mostly to a single territory, but do not scatter their dung or spray-urinate. Two dominant ♂♂ meeting at a mutual territory border engage in silent, repetitive horn-against-horn contacts interrupted by wiping the anterior horn on the ground. After periods varying from a few minutes to an hour or longer, the ♂♂ disengage back into their own territories. Fights may develop where a territory holder crossing a neighbouring territory on his return from water is accosted by a rival ♂, and unable to back away to his own territory. Otherwise territorial ♂♂ behave subordinately while off their home territory. Subordinate ♂♂ stand their ground with loud roars and shrieks when confronted by a territory holder, and hold their ground until the territory holder wanders off, having reinforced the dominance relationship. A ♂ displaced as territory holder may remain on as a subordinate, or seek to claim dominance in another territory. Fights can be quite severe, with ♂♂ battering one another around the head, belly and groin with their horns, and not uncommonly result in the death of the loser (Owen-Smith 1975).

White Rhinoceros *Ceratotherium simum*.

If a territory holder detects that a ♀ is about to enter oestrus, he attempts to hold her within his territory until receptivity develops. This entails blocking any movements by the ♀ and her companions to cross over a territory border region, accompanied by loud squeals by the ♂ and threatening roars in response by the ♀. This pro-oestrous consort period lasts a few days to two weeks or longer. Periodically the ♂ sniffs urine deposits, exhibiting the lip-curl (flehmen) posture, as well as dung from the ♀. Courtship begins with approaches by the ♂ accompanied by a hic-throbbing sound. Initially, the ♀ wards off such advances with aggressive roars. After several hours of repeated advances her aggression becomes muted, and the ♂ is able to rest his head on her rump. Eventually mounting, and ultimately intromission, takes place. Copulations last 15–30 min, with repeated ejaculations. A single mating is the rule, with the ♂ continuing to accompany the ♀ for a few more days thereafter without further advances. Subordinate ♂♂ may sometimes attempt courtship when a ♀ is not accompanied by a territory holder, but opportunities are rare and ♀♀ ward off advances from subordinate ♂♂ quite vigorously (Owen-Smith 1975).

The ♀ seeks the seclusion of dense bush, long grass or other remote areas prior to giving birth. Calves follow after the mother when just a few days old. They are very inquisitive, and young animals display great curiosity upon meeting other groups. Calves and subadults, and sometimes even adults of both sexes, may approach each other to engage in playful horn wrestling, and sometimes counter-chasing, for a period. Calves continue to accompany their mothers until around the time of birth of the next offspring (i.e. until about 2–3 years of age). The older calf may be driven off shortly before the birth of the new infant, but in low-density populations ♀♀ may rejoin the mother.

Subadults tend to settle in home-ranges similar in extent to those of adult ♀♀, but these are usually somewhat transient. Subadults form temporary associations with adult ♀♀ or other subadults, and these companionships enable them to explore a wider area than that covered by their own home-ranges, through what has been termed a 'buddy system' (Shrader & Owen-Smith

2002). By reducing the risk of being attacked by territory holders, and uncertainty of finding food in the novel area, such shifting companionships facilitate later dispersal by subadults beyond the region where they were born. Females establish fixed home-ranges around the time of birth of their first calf, ♂♂ when they settle within a territory either as a subordinate or eventually as a territory holder. During their adult period, ♂♂ alternate between territory holder and subordinate status. Testosterone levels are higher in territorial than in non-territorial ♂♂ (Rachlow *et al.* 1998). The average duration of territory tenure within a particular territory exceeds five years. Ageing ♂♂ may eventually settle in retirement within a territory as a subordinate and forego further aspirations to reproduction.

White Rhinos make a variety of sounds, the most frequently heard being the snorts and roars associated with maintaining spacing among individuals. The squeals made by ♂♂ blocking ♀♀ at territory boundaries resemble squeals made by calves seeking to nurse from their mothers. Soft pants serve as a contact sound between companions, and are also made by a mother calling a lost calf. Calves may also make high-pitched mewling sounds when moving. White Rhinos have no alarm call, animals communicate alarm to companions solely by their agitated movements, and in Garamba N. P. have been recorded stamping on the ground and kicking their bellies to make a drum-like sound.

White Rhinos are often found in association with Fork-tailed Drongos *Dicrurus adsimilis*, which hawk insects by flying along the sides of resting rhinoceros, and with Red-billed Oxpeckers *Buphagus erythrorhynchus*, which feed on ticks and skin secretions. The birds also give a harsh alarm call to which the rhinos react immediately by looking around agitatedly to detect the source of the birds' reaction. Any sound or movement causes the animals to run off. Rhinos may remain alert and sensitive to the slightest sound for half-an-hour or longer. Why the birds should give this alarm is not obvious, but the call may serve as a rallying signal in anticipation of their host running off due to some impending danger.

Reproduction and Population Structure In the wild ♀♀ undergo their first oestrous cycles around 4–5 years of age (youngest 3.8 years), and produce their first offspring around 6.5–7 years of age (Owen-Smith 1988, Hillman Smith 2006). In captivity, ♀♀ as young as 4.3 years have given birth (Rieches 1998), but perhaps only because they had reached near adult size by this age due to a high plane of nutrition. In the wild, ♂♂ show reproductive interest around eight years of age, but are not able to contest for territorial dominance until they reach full size around 10–12 years of age (Owen-Smith 1975). In captivity, ♂♂ as young as 4–5 years of age have sired offspring (Rieches 1998).

Births in the wild occur throughout the year, but there is a peak during the early dry season months (Mar–Jul in southern Africa and Dec–Mar in the northern subspecies) (Owen-Smith 1988, K. Hillman Smith pers. comm.). This seems to be an outcome of the stimulating influence of fresh grass growth induced by rainfall on oestrous cycling 16 months earlier, indicated by a marked rise in the number of ♀♀ being accompanied by ♂♂ from Oct–Nov when the wet season commences. During the dry season few ♀♀ show signs of oestrus, and dry spells during the wet season also suppress behavioural indications of oestrus. Hormone profiles obtained from faecal samples indicate that cycling continues, although at a lower amplitude, during these periods of ‘quiet oestrus’ (R. Swaisgood pers. comm.). Under captive conditions some ♀♀ show irregular oestrous cycles, while others go for long periods without overt reproductive activity, and some even switch off completely.

Reproductive activity almost never develops when White Rhinos are housed as male–female pairs in zoos, but the species is not difficult to breed when kept in groups in large enclosures. The presence of more than one ♂, or introduction of a new ♂, seems to be a requirement for ♀♀ to solicit matings (Lindemann 1982, Patton *et al.* 1999). This phenomenon, which enables ♀♀ to exert some control over their choice of a mate, probably operates in the wild as well.

Gestation lasts 16 months with a single offspring born. Calves weigh about 65 kg at birth (range 45–75 kg), or around 3.5% of maternal weight. At birth, the skin is pale grey with a pink tinge. The outer horny layer of the skin is moulted at about 1.5–4.0 months, revealing a new paler skin, and a further moult takes place at about 10 months (Bigalke *et al.* 1950). The calf is born hornless, but in one study animal the anterior horn pierced the skin at five weeks, grew to 39 mm at three months and 100 mm at seven months. Infants less than two months old nurse hourly, while among older calves nursing takes place about every 2.5 h. Calves start nibbling grass at around two months of age, while weaning off mother’s milk takes place from 12–18 months, although occasionally extends to 24 months. The milk is low in fat and protein and high in carbohydrates.

Cows come on heat again when the calf is about 6–12 months old, so that the modal inter-birth interval is 2–2.5 years (minimum 22 months in the wild when the previous calf survived) (Owen-Smith 1988); results from Garamba N. P. were similar, where inter-calf intervals averaged 30 months over a 20-year period, with a range of 21–57 months (Hillman Smith 2006). However, some ♀♀ appear less fertile and may undergo several oestrous cycles of about 30 days duration (range 27–34 days; R. Swaisgood pers. comm.) before conceiving. Hence, at a population level, the mean inter-calving interval is about 2.5 years (and see Rachlow & Berger 1998), or even longer under unfavourable conditions. However, under zoo conditions one ♀ produced six calves

in nine years at an average interval of 18.5 months (Lindemann 1982).

Cementum line counts from tooth sections indicate a maximum longevity of 40 years (Hillman Smith *et al.* 1986), which approximates maximum longevity of 45 years recorded in captivity (Weigl 2005). Elderly ♀♀ exhibit lengthened calving intervals, but one obviously very old ♀ gave birth after a long period with no offspring.

The overall sex ratio of the Hluhluwe–iMfolozi population was close to parity (98 ♂♂ to 100 ♀♀) based on the 1969 census, i.e. prior to distortion by removals. However, the sex ratio of calves born around this time showed a strong male bias (167 ♂♂ to 100 ♀♀, $n = 232$), which had moved up into older age classes by 1974. Early zoo records also show a bias towards male offspring (147 ♂♂ to 100 ♀♀, $n = 121$; Lindemann 1982), but this has not persisted (e.g. 43 ♂♂ to 42 ♀♀ born in San Diego Wild Animal Park; Rieches 1998). In Garamba N. P. there was a strong male bias in calves born during the disturbances of the war period, but overall the birth sex ratio was close to parity (K. Hillman Smith pers. comm.). At Hluhluwe–iMfolozi, primiparous ♀♀ produced mainly sons, and old ♀♀ mostly daughters. Hence the male-biased sex ratio of offspring may have been a temporary phenomenon related to the high proportion of young ♀♀ in the expanding population (Owen-Smith 1988).

Because ♂♂ reach maturity around 10–12 years of age and ♀♀ around 7–8 years, the functional sex ratio in Hluhluwe–iMfolozi in 1969 showed a female bias overall (80 adult ♂♂ to 100 adult ♀♀, $n = 684$). The predominance of ♀♀ and calves was greater in regions where high rhino densities occurred in favourable habitat, while in outlying areas of less suitable habitat there was an even sex ratio among adults. Subadults constituted 32%, and calves <3 years 22% (10% <1 year). Because the population was expanding at this time, it exhibited a higher proportion of young animals than would a stable population (Owen-Smith 1988). The structure of the expanding population in Garamba N. P. was similarly about 40 : 30 : 30% adults to subadults to calves (K. Hillman Smith pers. comm.).

Annual mortality in Hluhluwe–iMfolozi was 1% for adult ♀♀, 3.5% for adult ♂♂ and 3.5% for calves. Mortality appeared somewhat higher among subadults. However, these rates are for a growing population, at a time when few animals would be dying of old age. Much mortality among adult ♂♂ is as a result of fighting injuries, and some subadults are also attacked fatally by territory holders. Neonatal mortality was under 8%. Based on these mortality rates, and an effective natality rate of around 0.4 per adult ♀ per year, the maximum sustained rate of population growth is about 9% per year. The actual rate of increase of the Hluhluwe–iMfolozi population over 1960–72, adjusted for removals, was 9.5% per year, perhaps because the growing population had not yet attained a stable age distribution (Owen-Smith 1981, 1988). The Kruger N. P. population has also been growing at around 9% annually (SANParks pers. comm.). Similarly, between 1983 and 2005, 50 births were recorded in Garamba N. P., and mean annual rate of population growth was about 9% (Hillman Smith 2006). From comparison with other megaherbivores, population regulation is expected to occur largely through lengthened birth intervals coupled with retarded age at first reproduction. However, dispersal movements by subadults of both sexes make an important contribution to dampening local population increases. In Hluhluwe–iMfolozi population growth was slower in the high-density population core than in outlying areas. This indicated a dispersal rate outwards from the core of about 3% per year overall, and about 7.5% per year specifically for subadults (Owen-Smith 1988).

Predators, Parasites and Diseases Adult White Rhinos are effectively invulnerable to predation by carnivores. However, young animals are susceptible to being killed by Lions *Panthera leo* and perhaps Spotted Hyaenas *Crocuta crocuta*. They gain security by associating in groups, and when disturbed adopt a rump-against-rump formation facing outwards in different directions. When threatened by the close approach of a human, ♀ ♀ with young calves stand guard over the calf and do not charge. The long anterior horn could aid in warding off a predator attack. When fleeing, young calves gallop ahead of their mothers, enabling the mother to maintain close contact with the whereabouts of her offspring.

A new threat has developed following the introduction of orphaned young elephants into wildlife parks where White Rhinos occur. Young male elephants nearing adulthood have directed their sexual and aggressive behaviour towards White Rhinos of both sexes, with substantial numbers of rhinos being killed (e.g. Slotow & Van Dyk 2001, Slotow *et al.* 2001). Such incidents are seldom recorded in places like Kruger N. P. where a well-established population of elephants exists.

White Rhinos in southern Africa generally have large swarms of a large blood-sucking fly *Rhinomusca dutoiti* resting on their sides. These flies lay their eggs in rhino dung middens where their larvae develop. Much smaller flies of the genus *Lyperosia* are also commonly associated with rhinos and their middens. Large numbers of gyrostigmatid fly larvae, up to 40 mm long, may be found attached to the stomach walls of rhinos. Small piroplasms (*Babesia* and possibly also *Theilaria*) have been found in blood samples (Keep 1970). Circumstantial evidence indicates that the deaths of three rhinos translocated into Matusadona N. P. in N Zimbabwe were due to trypanosomiasis infection (Taylor 1986), and mortality among animals translocated to East Africa could have been due to the same cause.

Theiler (1962) provided a detailed checklist of ixodid ticks recorded from White Rhinos, and Baker & Keep (1970) a checklist from KwaZulu–Natal. More recently, Knapp *et al.* (1997) updated the lists with their own studies and recorded eight ixodid tick species known to infect White Rhinos in South Africa and seven in Zimbabwe, including *Amblyomma hebraeum*, *A. sparsum*, *Hyalomma marginatum*, *H. truncatum*, *Rhipicephalus maculatus* and *R. simus*. Walker (1991) mentioned that the adults of two species, *Amblyomma rhinocerotis* and *Dermacentor rhinocerotinus*, feed primarily on African rhinos. Penzhorn *et al.* (1994) provide a checklist of the helminths of White Rhinos. Ciliated intestinal protozoa are reported on by Van Hoven *et al.* (1988) and Obanda *et al.* (2008).

Conservation IUCN Category: Near Threatened (*Ceratotherium simum cottoni* – Critically Endangered A2abcd; B2ab(i,ii,iii,v); C1+2a(i,ii)b; D; E). CITES: Appendix I (excluding populations from South Africa and Swaziland, which are on Appendix II).

White Rhinos lived in abundance alongside indigenous peoples in southern Africa. The Zulus did not regard their flesh as edible and so did not hunt them. Only when white adventurers arrived with guns, and rhino hide and horns became a trade commodity, did the situation change. Animals were easily found by waiting at waterholes in the dry season, so that some hunters killed nearly 100 within a single year. Within about 50 years the southern subspecies was reduced to the verge of extinction. The last animals were shot in Botswana during the late 1870s and in Zimbabwe in 1893 (see Rookmaaker 2003b). A remnant pocket of White Rhinos surviving near the Umfolozi R. in South Africa was given legal protection when the Umfolozi G. R. was

proclaimed in 1897. A few individuals persisted in a remote region of Mozambique until the 1930s, when the last individuals were shot.

The first conservator claimed that only 20 White Rhinos remained in the then Umfolozi G. R. when he arrived in 1911. This was almost certainly an underestimate, because the first counts made around 1930 indicated a total population of over 200. Rookmaaker (2002) suggests that there were never less than 200 White Rhinos in Zululand before 1929. However, a founding remnant of 20–50 animals at the beginning of the twentieth century would be consistent with the subsequent population increase (Emslie & Brooks 2002b).

All surviving White Rhinos of the southern subspecies are derived from this remnant. Under protection the White Rhino population grew to reach about 550 in 1948, and about 1800 by 1968 (Emslie & Brooks 1999). Concerned by the risks associated with this single population, the then Natal Parks Board began trials on live capture using drugged darts in 1961. By 1970 a total of 730 White Rhino had been translocated to other parks, but 2000 animals still remained within the enlarged Hluhluwe–iMfolozi complex. The new concern was overpopulation within the now fenced confines of the protected area, which led to the study by Owen-Smith (1973). The immediate management response was an accelerated capture and removal programme, aimed at reducing the population below this high level, restocking the species through its former range, and supplying animals to various zoos (and see Player 1972).

The ecological recommendation from this research was to restrict White Rhino removals to designated dispersal sinks, or vacuum zones (Owen-Smith 1973, 1974, 1981). The aim was to allow the core population to adjust naturally to changing food resources while providing a safety outlet within the fenced area. This policy was eventually put into effect in 1985, but following several adjustments to the sink locations only became properly effective in 1998. Animals of suitable age classes and reproductive status settling within the sink areas are captured and offered for sale annually.

By December 2010, Southern White Rhino numbers stood at an estimated 20,160 (Emslie 2011), up from 6784 in 1993, 7532 in 1995, 8441 in 1997, 10,377 in 1999, 11,640 in 2001, 11,320 in 2003, 14,550 in 2005 and 17,475 in 2007 (Emslie & Brooks 1999, Emslie 2004a, Emslie *et al.* 2007, Milliken *et al.* 2009). The small drop between 2001 and 2003 does not reflect an actual decline in numbers as the difference is due to a lower population estimate for the biggest population (Kruger N. P.). There is no evidence of any actual decline in this park, and the difference is almost certainly an artefact of the sampling variability inherent in the method used to estimate numbers for this large population. Kruger's rhinos are descendants of just 336 founder animals (D. Pienaar pers. comm.). As of December 2010, South Africa held 93% (18,796) of the wild White Rhino population, predominantly in Kruger N. P. (10,500 animals) and Hluhluwe–iMfolozi Park (2312). While the state-run conservation agencies continue to manage most of the White Rhinos in Africa (72%), the private sector also manages a significant proportion (5504, 27%) with likely in excess of 5000 White Rhinos on private land in South Africa (AfRSG data unpubl.).

Around 1960–62, Garamba N. P. and surrounding reserves in NE DR Congo contained more than 1200 Northern White Rhinos, before armed rebels and others reduced the population to 100–200 during the rebellion following independence (Bourliere 1965, Curry-Lindahl 1972, K. Hillman Smith pers. comm.). White Rhinos increased again to about 500 in 1976 (Savidge *et al.* 1976), but between then and

1984 poaching for rhino horn reduced the population by 97% to just 15 animals (five adult ♀♀, six adult and one subadult ♂, and three juveniles) in the southern third of the park (Hillman Smith 2006). The Garamba Project was started in 1984, supported by a coalition of donors, and under protection the remnant population doubled to 30 by 1992 (0.015/km²), but following an upsurge in poaching from mid-2003 (11 carcasses were found in a three-month period between Mar and May 2004 alone), surveys counted only four individuals in the park and up to another four in an adjoining hunting area (Hillman Smith *et al.* 2003, Hillman Smith & Ndey 2005). Given the critical situation and unsustainable levels of poaching, an emergency plan to temporarily translocate five animals to a Kenyan sanctuary was developed, but this was not implemented due to internal political reasons. A survey in 2006 (Emslie *et al.* 2006) only counted two rhinos with another two different animals being seen subsequently. In recent years, there have been no signs or sightings of animals (one carcass was found in 2008), and it is feared this population is now extinct. Until the 1970s, White Rhinos were reportedly seen by hunters in E Central African Republic and S Chad, but their continued existence there seems unlikely. Fewer than 300 were estimated to occur in S Sudan in 1981, but this population also seems now extirpated (Hillman Smith 1981). The species became extinct in Uganda by 1982 (Edroma 1982).

CITES has downlisted South Africa's, and more recently Swaziland's, White Rhinos from Appendix I to Appendix II, allowing limited trade in live animals although not in products like horns. Hunting is permitted under strictly controlled conditions. Whether international trade in rhino horns should be allowed in order to generate funds to conserve this and other rhinoceros species effectively remains highly contentious, especially in the context of the hugely escalated illegal trade through 2009–12, due to rising demand particularly in Vietnam. In 2011 alone, around 450 individuals were killed by poachers, about half in Kruger N. P. Unless effective counteraction is implemented, further escalation of the killings could lead to a down-turn in the population trend of the species and reverse the conservation gains of the past.

Although captive breeding of Southern White Rhinos has been successful (but see Swaisgood *et al.* 2006), especially where a number of animals were held in large enclosures, captive reproduction of Northern White Rhinos has been less so. Emslie & Brooks (1999) noted the last birth among nine individuals held in two zoos had taken place in 1989 (Dvur Kralova in the Czech Republic, and at San Diego Zoo in the USA). At the time of going to press, the last four potential breeding animals from Dvur Kralove Zoo in Czech Republic had been introduced to a private reserve in Kenya. The animals are all related and the ♂♂ are very old, and the best that probably can be hoped for is to conserve some adaptive Northern White Rhino genes by inter-crossing with the southern subspecies. As of December 2005, there were more than 750 of the southern subspecies in zoos worldwide (Emslie *et al.* 2007).

Measurements

Ceratotherium simum simum

HB (♂♂): 3710 (3620–3800) mm, n = 3

HB (♀♀): 3480 (3370–3630) mm, n = 5

T (♂♂): 870 (700–1200) mm, n = 3

Sh. ht (♀♀): 1530–1770 mm, n = 3

WT: n. d.

Garamba N. P., DR Congo (K. Hillman Smith pers. comm.)

**Sexes combined

Body length increases with age and approaches an asymptote at around 14 years, but chest girth only attains an asymptote at around 20 years (Rachlow 1997)

Skull and horn measurements:

Ceratotherium simum simum

Anterior basal circumference (♂♂): 730.4 ± 65.0 mm, n = 65

Anterior basal circumference (♀♀): 610.0 ± 34.4 mm, n = 39

Anterior horn length (♂♂): 583.4 ± 141.9 mm, n = 72

Anterior horn length (♀♀): 589.4 ± 98.0 mm, n = 107

Anterior horn WT (♂♂): 6.1 ± 1.8 kg, n = 91

Anterior horn WT (♀♀): 4.0 ± 1.5 kg, n = 33

Posterior horn WT (♂♂): 2.2 ± 1.1 kg (n = 69)

Posterior horn WT (♀♀): 1.2 ± 0.7 kg (n = 19)

Kruger N. P., South Africa (Pienaar *et al.* 1991, Pienaar 1993)

Anterior horn length (♂♂): 640 (620–660) mm, n = 4

Anterior horn length (♀♀): 720 (620–820) mm, n = 5

Posterior horn length (♂♂): 310 (270–390) mm, n = 3

Posterior horn length (♀♀): 200 (160–260) mm, n = 5

KwaZulu–Natal, South Africa (Owen-Smith 1973)

Ceratotherium simum cottoni

Anterior horn length (♂♂): 650 (560–740) mm, n = 4

Anterior horn length (♀♀): 540 (480–590) mm, n = 4

Posterior horn length (♂♂): 195 (143–235) mm, n = 4

Posterior horn length (♀♀): 194 (180–210) mm, n = 4

Garamba N. P., DR Congo (K. Hillman Smith pers. comm.)

The record length for the Southern White Rhino is an animal from South Africa which had a front horn measuring 1581 mm; its accompanying rear horn was 566 mm. For the Northern White Rhino, the record front horn length is 1273 mm and 559 mm for the rear, for an animal from East Africa (Selous 1899).

GENUS *Diceros* Black Rhinoceros

Diceros J. E. Gray, 1821. London Med. Repos. 15: 306.

Diceros is a polytypic genus, represented by a single extant species, the Black Rhinoceros *Diceros bicornis*. This species once was widespread in sub-Saharan Africa, from the Niger R. in the west to Somalia in the north-east, and southwards to South Africa. It was never found in the Congolese rainforests. The animal exists in a large variety of habitats, including savanna, bushveld and dry thornbush, from sea-level to high mountain forests.

The members of *Diceros*, like the other extant African rhinoceros genus *Ceratotherium*, bear two nasal horns. *Diceros* is distinguished from *Ceratotherium* by the shorter skull, pointed upper lip, swayed back, and generally smaller size (Guggisberg 1966, Hillman Smith & Groves 1994, Joubert 1996). The extinct rhino from the regions around the Cape of Good Hope was larger than other populations (Rookmaaker & Groves 1978). Inter-specific hybridization has occurred between a female *Ceratotherium simum simum* and a male *Diceros bicornis* kept in an 800 ha enclosure of South Africa's National Zoological Gardens Game Breeding Centre (Robinson *et al.* 2005).

Fossil remains of species referable to *Diceros* have been found in many parts of Africa. *Diceros douariensis* was found in the Mio-Pliocene of Tunisia (Guérin 1966) and *Diceros australis* in deposits of the middle Miocene of Namibia (Guérin 2000). In East Africa, the genus was represented by *Diceros praecox* in the early to late Pliocene

Black Rhinoceros *Diceros bicornis*.

(Geraads 2005), although previously some of the remains had been classified under *Ceratotherium* (Hooijer & Patterson 1972). *Diceros bicornis* first appears at the 4 mya level in Pliocene deposits in Kenya and Ethiopia, and at 2.5 mya the molar crowns became as high as in the recent specimens (Hooijer 1978, Prothero *et al.* 1986).

Kees Rookmaaker

Diceros bicornis BLACK RHINOCEROS (BROWSE RHINOCEROS, HOOK-LIPPED RHINOCEROS)

Fr. Rhinoceros noir; Ger. Spitzmaul-Nashorn

Diceros bicornis (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 56. 'Habitat in India', but Cape of Good Hope, fide Thomas (1911).

Taxonomy Groves (1967) reviewed earlier classifications and reduced the number of subspecies recognized based on cranial dimensions and other characters to seven in different regions of Africa. This classification has since been questioned, as it was based on small sample sizes (du Toit 1986), and was not supported by a preliminary analysis of data from more skulls (du Toit 1987). A proposal from a 1986 African Rhino Workshop in Cincinnati was adopted by the first IUCN African Elephant and Rhino Action Plan (Cumming *et al.* 1990) resulting in the recognition of four Black Rhino ecotypes or 'subspecies' conservation units (Cumming *et al.* 1990). The IUCN Species Survival Commission's African Rhino Specialist Group recognized these four subspecies conservation units in different areas (Emslie & Brooks 1999) although only three survive: Southern-central (*Diceros bicornis minor*); South-western (*D. b. bicornis*); and Eastern (*D. b. michaeli*); the Western (*D. b. longipes*) was recently declared extinct.

Historically, the boundaries between these subspecies were not 'hard-edged', in contrast to the markedly discontinuous range of the two White Rhinoceros *Ceratotherium simum* subspecies. However, there are major differences in the habitat and climates in the core areas of the three remaining subspecies, and it is likely that each has specific genetic or behavioural adaptations to the environment. While some conservationists have preferred to refer to the Black Rhino subspecies as ecotypes due to their contiguous distribution and perceived

limited genetic differences between them, genetic analyses indicate that the Southern-central, South-western and Eastern Black Rhino are sufficiently distinct to support the current subspecies distinction (Harley *et al.* 2005). The more discontinuous distribution of the recently extinct Western Black Rhino, and the single genetic sample analysed to date, support its classification as a separate subspecies (Harley *et al.* 2005). Genetic variation in mitochondrial DNA of *D. b. minor* (from Zimbabwe animals) and *D. b. michaeli* (from East Africa) revealed that these two subspecies represent separate ancestral lineages, which diverged between 0.93 and 1.3 million years (Brown & Houlden 2000). These genetic studies support recognition of four subspecies, although K. Rookmaaker (pers. comm.) notes they too were also based on small sample sizes and ignored many populations.

Controversy surrounds the formal subspecies nomenclature. *Diceros b. bicornis* has been described as being restricted to the Western Cape and further north, at least to middle Namibia, and is believed to have gone extinct (Ansell 1974, Rookmaaker & Groves 1978) leading to a questioning of the use of the subspecies name *D. b. bicornis* to refer to the animals derived from the surviving arid-adapted animals from N Namibia (Hopwood 1939, Groves 1967, Rookmaaker 2005b, P. Lloyd pers. comm.). However, this view has been challenged. It has been argued that the animals from N Namibia can be amalgamated with those in the Western Cape and

S Namibia that died out (Hall-Martin 1985, Du Toit 1987), on the basis that (1) the largest skulls Du Toit (1987) measured were from N Namibian animals, which was in keeping with Rookmaaker & Groves' (1978) description of *D. b. bicornis* in the Western Cape and S Namibia as a very large rhino; and (2) on the ecological similarities between the earlier postulated range of *D. b. bicornis* and that of extant Namibian rhino (Hall-Martin 1985). Further evidence supporting this amalgamation (which may be correct; Rookmaaker 1996) comes from an old map of Greater Kudu *Tragelaphus strepsiceros* distribution in Namibia (Shortridge 1934), which shows this species had a contiguous distribution along the Molopo, Nossob, Oliphant, Auob, Great Fish and Orange Rivers (i.e. all the way to the south of the country and well into the supposed range of *D. b. bicornis*). Dietary overlap (for both species and size classes) between Greater Kudu and Black Rhino can be quite considerable (Macfarlane 1997), and it has been noted that where Greater Kudu generally do well, the Black Rhino normally also thrives. For these reasons, it is quite possible that at one time there may have been a continuous distribution of Black Rhinos from N Namibia all the way to the Western Cape supporting the current use of the *D. b. bicornis* subspecies name (although much of the clinal genetic variation in the southern part of the range will have been lost). This is the view currently adopted by the SADC Rhino Management Group (SADC RMG).

The current boundary between the South-western and Southern-central subspecies in southern Africa is somewhat arbitrary, imperfectly known and is primarily a practical construct given that all populations of these two subspecies in South Africa outside of Hluhluwe–iMfolozi and uMkhuze in KwaZulu–Natal have been reintroduced. Following from earlier Conservation Plans, the South-western Black Rhino is today considered as the most arid-adapted subspecies. In earlier versions of the South African Black Rhino management plan, the SADC RMG, which manages the plan, used the 400 mm isohyet from Dent *et al.*'s (1989) mean annual precipitation map in Schulze (1997) as the primary basis for setting a putative east/west subspecies boundary in the Eastern Cape. However, since 2007, the subspecies boundary in the Eastern Cape has been revised to take into account the probable impact of a 'Transkei Gap' on rhino movement. This area, in the north-east of the province north of the Kei R., has now been classified as extralimital, and no new populations of Black Rhino will be allowed to be established in this area. The remainder of the province is now designated as *D. b. bicornis* range together with the Western Cape and Northern Cape provinces. Although no new populations will be countenanced, any existing Eastern Cape *D. b. minor* populations are being allowed to remain. Other provinces are demarcated as *D. b. minor* range. Rhinos in the miombo woodlands of the Selous G. R. in S Tanzania are classified as being Southern-central Black Rhinos, while the populations in N Tanzanian areas with more nutrient-rich soils and a dual wet season are classified as being Eastern Black Rhinos. While these classifications of Tanzanian Black Rhinos on habitat and climatic grounds, as well as surviving populations' proximity to rhino populations in neighbouring countries seems reasonable, there have been no genetic analyses to test their validity. Rookmaaker (2005b, pers comm.) argues that due to changes in the perceived geographical ranges for the four groups, and the Principle of Priority, Code of Zoological Nomenclature (4th edition para 23), *D. b. minor* and *D. b. michaeli*

should automatically be renamed *D. b. keitloa* and *D. b. brucii*, respectively (given the current AfRSG subspecies classification and distribution). On account of such concerns about the current classification and subspecies distributions, a continent-wide revision of Black Rhino taxonomy is needed.

Synonyms: *africanus*, *angolensis*, *atbarensis*, *brucii*, *camperi*, *capensis*, *chobiensis*, *gordoni*, *holmwoodi*, *keitloa*, *ketloa*, *ladoensis*, *longipes*, *major*, *michaeli*, *minor*, *niger*, *nyasae*, *occidentalis*, *palustris*, *platyceros*, *pleioceros*, *porrhoceros*, *punyana*, *rendilis*, *somaliensis*. Chromosome number: $2n = 84$; the X chromosome is a large submetacentric (Hungerford *et al.* 1967, Heinichen 1969b, Houck *et al.* 1995). Robinson *et al.* (2005) have recently confirmed a case of inter-specific hybridization in rhinoceroses, wherein a calf was born to a young White Rhino cow and a Black Rhino bull held together in a small enclosure (without an adult White Rhino bull being present); the hybrid showed a mixture of phenotypic traits characteristic of the two species, including ear shape resembling that of the Black Rhino, an upper-lip more in keeping with the shape of the White Rhino (but also exhibiting a small upper-lip protrusion, not unlike the prehensile lip in the Black Rhino), and head length was intermediate between the two. It is not known if the hybrid was reproductively impaired.

Description Second smallest of the rhino species, with the Sumatran Rhino *Dicerorhinus sumatrensis* being smaller. Stands about 1.6 m at the shoulder and has a mass of around 800–1350 kg. Sometimes known as the Hook-lipped Rhino on account of its hooked prehensile upper lip, which it can use like an elephant's trunk to grab hold of branches and pull them into the mouth (unlike the grazing White Rhino, the Black Rhino is a browser eating primarily trees, bushes, herbs and succulents). In silhouette the neck hump is not as pronounced as that of the White Rhino. The much smaller head is generally held higher than the White Rhino, unless feeding at ground level. Back has a much more concave saddle-like appearance in profile compared with the White Rhino whose prominent vertebral crest two-thirds of the way along the back is much more pronounced. Ears rounded and trumpet-shaped, tips pointing upwards from the middle of the ear. Ears fringed with hair (as in the White Rhino), and the amount of hair on the ears varies between individuals. Body hairs otherwise sparse. Body barrel-shaped due to an extended ribcage. Overall body colour a marginally darker battleship grey than that of the White Rhino. However both species of rhino can take on the colour of the soil and mud in which they have been wallowing. Eastern subspecies has marked rib-like skin folds on its flanks. There are also prominent folds of skin near the top of the forelimbs, and where the upper part of each hindlimb joins the body. Limbs thickset with three toes on each foot, each with large nails that mark clearly in the spoor. Toes and feet smaller than those of the White Rhino and so spoor of the Black Rhino is smaller, more rounded and with smaller toe prints compared with the White Rhino, whose spoor is more elongated in appearance with a more pronounced groove in the middle of the back of the print. Cushioned pads on the soles of the feet have a hard surface with a mosaic of irregular cracks; the patterns can be used to identify individual animals for short periods of time, as they can change. Tail is short with a sparse fringe of bristly hairs. Some animals may miss part of their tails, and it is thought this is caused by unsuccessful hunting attempts by Spotted Hyenas *Crocuta crocuta*.

Black Rhinoceros *Diceros bicornis*.

Two horns present on snout; these are made up of compressed keratinous fibres and do not have a bony core. In general, the anterior horn is invariably longer than the posterior horn. For example, in Hluhluwe–iMfolozi in 1973 only 2.5% of ♂♂ had anterior horns equal in length to the posterior, and none shorter ($n = 120$); in 1985, no ♂♂ had anterior horns equal in length or shorter than the posterior. Incidence is slightly higher for ♀♀: 5.7% shorter in 1973 ($n = 106$) and 4.3% in 1985 ($n = 69$) (Hitchins 1989). Horn length and basal circumference greater in adult ♂♂ than in adult ♀♀. In a sample of horns from KwaZulu–Natal and Kruger N. P., the mass of anterior and posterior horns amounted to some 2.65 kg of horn per animal (Pienaar *et al.* 1991, Pienaar 1993; see Horn Measurements). Base of the anterior horn is circular in shape in contrast to the White Rhino, whose anterior horn has a squarish base. In general Black Rhino horns are thinner and less chunky than White Rhino horns. Intrinsic anterior horn growth is similar to the White Rhino (Pienaar *et al.* 1991, Rachlow & Berger 1997). Berger *et al.* (1993) determined regrowth rates for dehorned Black Rhino at 60 mm and 27 mm per year for anterior and posterior horns, respectively; regrowth was more rapid in juveniles, at 89 mm and 44 mm per year, respectively. Horns from both African species are much larger than those of the three Asian species. Chemistry (carbon and nitrogen isotope ratios) of rhino horn differs between the two species reflecting their different diets (Lee-Thorp *et al.* 1992, Emslie *et al.* 2001, Amin *et al.* 2003).

Females bear two inguinal nipples. Males lack a scrotum, and the muscular penis points backwards when enclosed in its sheath. Apart from genitalia, there is little sexual dimorphism, except that ♂♂ attain a bigger body mass than ♀♀, and have noticeably more heavily set chests and necks. In the Southern-central Black Rhino, ♀♀ invariably have thinner longer horns compared with adult ♂♂, which tend to have shorter chunkier horns. However, Eastern Black Rhino horns do not clearly exhibit this trend.

Rhinoceros forelimbs.

Skull is shorter than that of the White Rhino, the supraoccipital crest not extending upwards and backwards to the extent seen in the White Rhino. Occipital crest lacks broad rugose area on top characteristic of the White Rhino, while zygomatic arches are heavily built to give a firm attachment for the masseter muscles that activate the massive lower jaw. The adult dental formula is $I^{0/0}, C^{0/0}, P^{4/3-4}, M^{3/3} = 26-28$. One to two lower incisors in the deciduous dentition. In the adult dentition, sometimes only three premolars are present in the upper and lower jaws. Upper and lower second molars are the largest of the cheekteeth (Skinner & Chimimba 2005). Goddard (1970b) and Hitchins (1978) describe patterns of tooth eruption and toothwear patterns. A slightly modified version of Hitchins' (1978) visual scale together with using horn configuration information (Module 6 of Adcock & Emslie 2004) has become the standardized method used for visually ageing animals across the continent using a six category A–F scale.

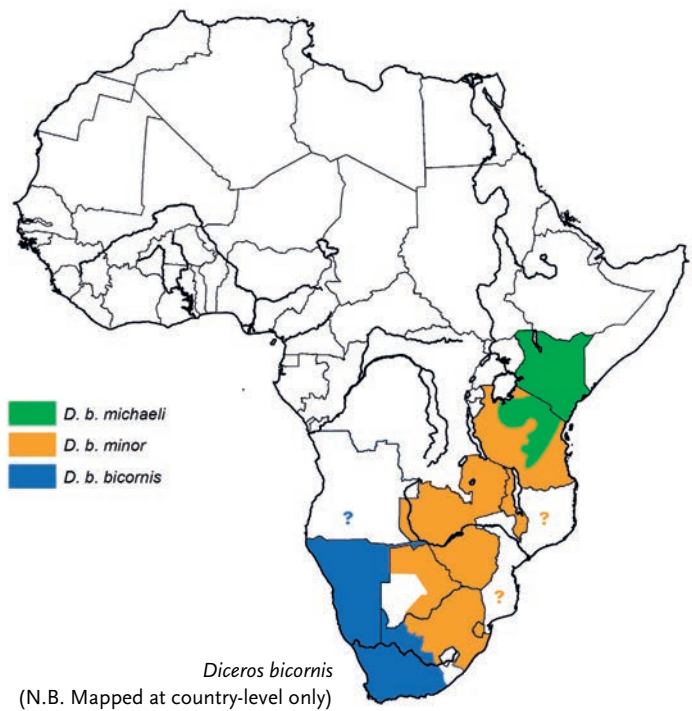

Lateral, palatal and dorsal views of skull of Black Rhinoceros *Diceros bicornis*.

Geographic Variation

D. b. longipes (Western Black Rhino). Formerly occurred in the savanna of central–West Africa, and latterly confined to N Cameroon; recently declared extinct by the IUCN following the failure of surveys to find any surviving individuals. Slightly longer legs relative to body length (hence the subspecies name *D. b. longipes*). The high degree of homozygosity across the nine loci studied in the single Western Black Rhino sample showed the least genetic diversity of all the individuals examined, and was consistent with a major loss of genetic diversity in this population (Harley *et al.* 2005).

D. b. michaeli (Eastern Black Rhino): historically, in S Sudan, Ethiopia, Somalia to Kenya, NC Tanzania and Rwanda; currently only confirmed surviving in Kenya, N Tanzania and Rwanda, with an extralimital population established in South Africa in Limpopo Province. Longer, more slender and more curved horns than the two southern subspecies; noticeable skin folds, which resemble ribs on its flanks (these folds are not obvious in the other subspecies).

D. b. minor (Southern-central Black Rhino): KwaZulu–Natal in South Africa through Swaziland, Mozambique (where now possibly extinct), Zimbabwe, N Botswana (reintroduced), and Malawi into W and S Tanzania. Formerly in N Angola and S DR Congo. Smallest of the subspecies and in some parts of its range is vulnerable to developing large red sores on its chest (see Predators, Parasites and Diseases).

D. b. bicornis (South-western Black Rhino): formerly in Namibia, S Angola, W Botswana and Western Cape and Eastern Cape, south of Kei R. (South Africa), though now extinct in Botswana with perhaps a few individuals surviving in S Angola. Largest of the subspecies; in some parts of the range, and most noticeably in the very arid west Kunene region in NE Namibia, often possesses very thick straight horns (the anterior horns of other Black Rhino subspecies are invariably slim and curved when the animal is adult).

Similar Species

Ceratotherium simum. Sympatric over various parts of the range of the Southern White Rhino (although historically had a more restricted distribution than the Black Rhino). Considerably larger, with lips broadly squared rather than hooked upper lip (indicative of its preference for graze not browse); pronounced nuchal hump visible when the head is raised; skull longer and narrower, with occipital part produced backwards beyond the condyles; high crowned molars and premolars adapted for grazing; more-pointed ears, with tips pointing sideways from the outside edge of the ear.

Distribution

Historical Distribution The probable distribution of the Black Rhinoceros ca. 1700 encompassed pretty much the whole of southern and eastern Africa, including S Angola, and all but the arid south-west strip of Namibia and the north-western parts of Zambia. The far east of DR Congo served as the probable western edge of the distribution with a northernmost distributional band (500–1000 km wide) stretching westwards from S Somalia through Ethiopia, S Sudan, S Chad, N Central African Republic, N Cameroon and N Nigeria (see Cumming *et al.* 1990, Emslie & Brooks 1999).

The former westerly limit of the species, and its distribution in West Africa as a whole, has been investigated by Rookmaaker (2004), who could find no evidence of the existence of the species in Senegal, Gambia, Mali, Guinea Bissau, Guinea, Sierra Leone, or from Ghana,

Togo and Benin. In addition, evidence from Liberia and Burkina Faso mainly rested upon the existence of indigenous names for the species in these countries. Furthermore, records from N Côte d'Ivoire could not be substantiated, the sighting of tracks in 1853 by Heinrich Barth in Niger on the western bank of the river seemingly the only reliable evidence from that region. Based on this, Rookmaaker (2004) proposed two options for the historical distribution of the Black Rhino in 1700 (perhaps coinciding with that in 1900): first, on the basis of the footprints seen by Barth, the species may have occurred westward up to longitude 1°E near the Niger R.; or, second, the western boundary of the range could be placed some 700 km further eastward in the north-central part of Nigeria.

Early in the nineteenth century, the Black Rhino was still the most numerous of the world's rhino species, with several hundred thousand rhinos roaming the African continent from central–West Africa to the slopes of Table Mountain in the far south (Emslie & Brooks 1999). Early European travellers reported Black Rhino to be both widespread and common throughout much of the continent.

Current Distribution Whereas in 1980, Tanzania, Zambia and the Central African Republic were the major range states for the Black Rhino (probably holding around two-thirds of the continent's animals), currently, 98% of the continent's wild Black Rhinos occur in four range states: South Africa, Namibia, Zimbabwe and Kenya (Milliken *et al.* 2009). The same four states also conserve 96% of Africa's wild White Rhinos (Milliken *et al.* 2009). Today, the Black Rhino is extinct in the Central African Republic, and, with the failure of recent surveys to locate any surviving individuals in N Cameroon, has been declared extinct. Smaller numbers of Black Rhinos occur in Tanzania, while small numbers have also been reintroduced into Malawi, N Botswana, Swaziland and Zambia. A very few Black Rhino have been reported to survive in S Angola, while a single animal has been seen in Mozambique (Emslie 2011). A lone individual in Akagera N.P., Rwanda (Milliken *et al.* 2009) has now died; presence in Ethiopia has not been confirmed.

Habitat The Black Rhino can occur wherever herb and woody browse occurs in sufficient amounts to support a population. As a result, Black Rhinos can survive in a wide range of habitats, including deserts, semi-deserts, wooded savannas, woodlands, forests and even sub-alpine heathlands (up to 3700 m on Mt Kenya; Young & Evans 1993). They occur in areas with average annual rainfalls from 100 mm to 1300 mm. The density at which they can exist in these habitats varies over 100-fold, from less than 1 rhino per 100 km² in the desert plains of Western Kunene (Hearn 1999) to more than 1 rhino per 1 km² in the best thicket vegetation. Historically, the highest densities have been found in *Commiphora/Bauhinia* thickets in Tsavo West, Kenya (Goddard 1970a), *Acacia* thickets in Hluhluwe, South Africa in the 1960s (Hitchins 1969), and deciduous thickets in the middle Zambezi Valley in the 1960s (Jarman 1971). These latter areas have annual rainfalls of 600–900 mm. In East Africa, patches of ground-water forest marked by an overstorey of *Acacia xanthophloea* and a dense year-round understorey herb and shrub layer also support very high rhino densities, such as Lake Nakuru N. P., Kenya (Kenyan Rhino Programme data) and Lerai forests of Ngorongoro Crater (Goddard 1967), although currently the forest in the crater is rarely used by rhinos, for which the most plausible explanation is that there is less cover since the 1960s, and greater competition for browse and

disturbance from Savanna Elephants *Loxodonta africana* (Mills *et al.* 2006). Succulent valley bushveld also currently provides high quality habitat. In contrast, rhinos occur at low densities in the open East African savanna grassland habitats within the Serengeti–Mara ecosystem, where browse availability is very sparse (Frame 1980, Walpole *et al.* 2001, Adcock *et al.* 2005).

Intermediate rhino carrying capacities of 0.25–0.5 Black Rhino per km² occur in some Kenyan areas, woodland areas in the northern and western Serengeti, succulent valley bushveld in the Eastern Cape and Zululand thornveld (Adcock 2001, Adcock *et al.* 2005). Nutrient-poor habitats including broadleaved miombo woodlands have low carrying capacities. In some parts of southern Africa, frost also reduces Black Rhino carrying capacity. Black Rhino carrying capacities over much of southern Africa are only in the region of 0.1 rhino/km².

The availability of good and intermediate quality browse is the main factor determining Black Rhino density in a habitat (Adcock 2001). How fast the browse grows also influences carrying capacity, and this is determined by amounts of annual rainfall, rainfall seasonality, minimum temperatures, the fertility of the soil and the resulting plant species composition (Adcock 2001). The proportional plant species composition of the available browse and its palatability to the Black Rhino are also important (Adcock 2001, Buk 2004).

Black Rhinos are water-dependent in the majority of habitats, and rhino home-ranges are arranged relative to permanent water sources in an area. Rhinos can, however, move a fair distance from water within their range. In Etosha N. P., only 1.1% of aerial Black Rhino sightings were greater than 14 km from water (R. H. Emslie *et al.* pers. obs.). In other areas, rhinos prefer to stay within 4–8 km of water (Buk 2004, K. Adcock pers. obs.). However, where sufficient water-containing succulent vegetation occurs, Black Rhinos can survive for several months in the total absence of surface water (Olduvai Gorge, Tanzania, Goddard 1968; Liwonde N. P., Malawi, R. Bhima pers. comm.).

Abundance It has been estimated that there may have been as many as 850,000 Black Rhinos in Africa around 1700 (Adcock & Emslie 2004), and throughout most of the twentieth century the Black Rhino was still the most numerous of the world's rhino species. However, relentless hunting of the species and clearance of land for settlement and agriculture resulted in the population being reduced from a probable several hundred thousand at the start of the century. There may still have been as many as 100,000 animals in Africa in 1960, but by 1970 it was estimated that there were only 65,000 left, at which time Kenya still had some 16,000–20,000 animals (Martin & Martin 1982).

Between 1970 and 1992 large-scale poaching caused a dramatic 96% collapse in numbers. The most important cause of this decline was a dramatic increase in the price of rhino horn (Leader-Williams 1988). From 1992 to 1995 total numbers remained relatively stable with increases in some countries (those with the best protected and managed populations) being negated by declines in others. The minimum population estimate in 1995 was approximately 2410 (Emslie & Brooks 1999). Since 1995, Black Rhino numbers at a continental level have steadily increased, reaching 3610 by the end of 2003 (Emslie 2004a), 3725 by December 2005 (Emslie *et al.* 2007), 4230 by December 2007 (Milliken *et al.* 2009) and 4880 by 2010 (Emslie 2011). Two countries have shown net increases in numbers of Black Rhinos over the period 1980–2010: South Africa and Namibia, from estimated 630+300 in 1980 (Emslie & Brooks 1999) to 1915+1750,

Black Rhinoceros *Diceros bicornis* detail of head myology.

respectively, in 2010 (Emslie 2011). In both countries, investments in conservation programmes, including monitoring and law enforcement, have been high. As of December 2005, an additional 240 Black Rhino (171 *D. b. michaeli* and 69 *D. b. minor*) occurred in captivity worldwide (Emslie *et al.* 2007).

Table 8 gives the December 2010 population estimates (excluding speculative guesstimates) by subspecies by country compiled by IUCN/SSC's African Rhino Specialist Group as of December 31, 2010 (Emslie 2011).

Adaptations Black Rhinos have very good hearing and sense of smell, but their eyesight is poor. Animals can react to a person walking past in clear view at ranges of 60 m, yet if the wind direction is favourable they appear unable to identify a motionless human observer (especially if the person's shape does not contrast with the surroundings) at ranges greater than around 30 m (Schenkel & Schenkel-Hullinger 1969). Black Rhinos downwind of man have been known to react at a distance of 800 m, and in most instances sound or smell will alert rhinos to the presence of humans rather than sight (Schenkel & Schenkel-Hullinger 1969). Sometimes, the screeching of oxpeckers

Black Rhinoceros *Diceros bicornis* skeleton.

Buphagus spp. can alert rhinos to the nearby presence of a human.

The prehensile upper lip is an adaptation that facilitates browsing. The lip is used in much the same way as an elephant uses its trunk to grab and pull browse into the mouth. As in the White Rhino, the big heavy skull, absence of incisor and canine teeth in both jaws, and high-crowned premolars and molars, possessing convoluted enamel layers on their biting surfaces, are adaptations for grinding up coarse food. The Black Rhino is a hindgut fermenter with a capacious large caecum where digestion of plant fibre occurs (and see Clemens & Maloiy 1982).

The skin is thick, and being large animals rhinos have an unfavourable surface area to body-weight ratio making thermoregulation difficult and important. In the heat of the day, they often lie up in wallows, under shady trees, or in areas of closed thicket/woodland. They also like to lie up on ridge tops where they can take advantage of any breezes. A subcutaneous layer of fat and muscle builds up as the condition of the animal improves, providing a buffer against malnutrition during the dry season. Wallowing in mud may condition the skin and give some protection against biting flies whilst also trapping many ticks in mud, which can then get rubbed off against favoured trees/tree stumps or rubbing rocks. Trees and rocks are also used to relieve itches, particularly inside the legs, the chest, around the base of the horns and along the flanks.

In the dry season, when surface water is limited, Black Rhinos may only drink on average every 2–3 days (P. Erb pers. comm).

Table 8. Population estimates by subspecies and by country of Black Rhinoceros (December 2010).

| Country | <i>D. b. bicornis</i>
(South-western) | <i>D. b. michaeli</i>
(Eastern) | <i>D. b. minor</i>
(Southern-central) | Total |
|--------------|--|------------------------------------|--|-------------|
| Angola | 1 | | 1 | 1 |
| Botswana | | | 7 | 7 |
| Kenya | | 594 | | 594 |
| Malawi | | | 24 | 24 |
| Mozambique | | | 1 | 1 |
| Namibia | 1750 | | | 1750 |
| South Africa | 171 | 60* | 1684 | 1915 |
| Swaziland | | | 17 | 17 |
| Tanzania | | 88 | 25 | 113 |
| Zambia | | | 27 | 27 |
| Zimbabwe | | | 431 | 431 |
| Total | 1920 | 740 | 2220 | 4880 |

*The *D. b. michaeli* population in South Africa is out of range.

Drinking generally takes place during the early evening through to early morning, so that travelling to and from water occurs during the cooler hours; in Namibia, 64–100% of drinking occurs between sunset and midnight (P. Erb pers. comm.). Black Rhinos also appear to do much of their feeding when it is dark, and this may aid thermoregulation as well as allow animals to feed more easily in more exposed areas.

Despite their large size, Black Rhinos can gallop at an estimated 55 km/h when charging or fleeing from danger. They are more prone to charge intruders than White Rhinos; however, Black Rhinos will often turn and run away from danger, especially if this is downhill and they can run into cover. When disturbed they are also likely to run further than White Rhinos before stopping. Individual Black Rhinos are idiosyncratic, and while some individuals can be aggressive and may frequently charge people or even vehicles, others are placid and tolerate human activity in their vicinity.

Foraging and Food Black Rhinos are browsers, consuming primarily woody plants and herbs. Grass is generally only eaten incidentally while foraging for low-growing herbs, but new soft grass leaf growth is voluntarily taken on occasion, and can form over 10% of the wet-season diet (Goddard 1968). A wide range of browse species eaten in any given habitat, but while over 100 species may be ingested during a year's foraging, 90% of the diet commonly comprises fewer than 20 species (Hall-Martin *et al.* 1982, Loutit *et al.* 1987, Kotze & Zacharias 1993, Oloo *et al.* 1994, Emslie 1999, Breebart 2000, Brown 2004, Buk 2004).

Species from the families Euphorbiaceae and Tiliaceae, and the Mimosoideae and Papilionoideae subfamilies of the legumes, are important in the diet in most ecosystems. Plant species of the genera *Euphorbia*, *Grewia* and *Acacia* are particularly important and preferred, and *Spirostachys* and *Acalypha* feature prominently among the genera of Euphorbiaceae eaten. Among the more herbaceous plant forms favoured by Black Rhinos, species from the Acanthaceae, Amaranthaceae and Malvaceae family feature strongly, including species from *Barlaria*, *Blepharis*, *Acaranthus*, *Amaranthus*, *Cyathula*, *Hibiscus*, *Pavonia*, *Sida* and *Abutilon*.

A wide diversity of secondary plant chemicals occur in Black Rhino browse species, many of which are potentially harmful. The ability to cope with these chemicals is an interesting feature of their feeding ecology that is not well understood. Black Rhinos produce tannin-binding saliva in response to food types rich in tannins (Napier 1998). The large liver also plays an important role in metabolizing a wide range of chemicals, but they still need to balance their exposure to any one chemical, which they seem to do by limiting intake of some plant species types (even if favoured) and diluting such intake with browse containing different chemicals (e.g. *Spirostachys africana*, Emslie 1999). However, coping with high levels of tannin-type secondary plant chemicals carries a cost, increasing mineral usage (e.g. nitrogen; Illius & Jessop 1995), and negatively affecting food digestibility and mineral and energy uptake (Jansman 1993, Shung-MacCoubrey *et al.* 1997). In habitats on nutrient-poor geologies, where the bulk of available browse biomass contains significant levels of secondary chemicals (polyphenols and tannins), Black Rhino densities are lower than expected from their rainfall and apparent browse availability characteristics alone (Adcock 2001). In Nairobi N. P. Black Rhinos were found to select for plants with low phenol and alkaloid contents (Muya & Ogue 2000).

Black Rhinos feed within a specific height range. About 98% of their intake is from browse located within 2 m of the ground, and the 0.5–1.5 m height range is most preferred (Kotze & Zacharias 1993, Macfarlane 1997, Emslie 1999, Breebart 2000, Brown 2004, Buk 2004). They do, however, push over trees, especially those with a spindly growth form, to access browse above 2 m. High branches can also be pulled or broken down to feed on. Because smaller size classes of most woody species are preferred, tall, rank grass growth (common in higher-rainfall ecosystems) can substantially interfere with feeding. This can lead to rhinos avoiding areas of long grass altogether, or to feed on less-preferred, taller plants instead (Emslie 1999). In captivity, they have been recorded feeding on an average of 37.8 ± 9.0 kg (wet mass) of thorny, woody plants per day (Maddock *et al.* 1995). The dung boluses contain much coarse woody material, which exhibits the characteristic neat pruning of twigs at a 30–45° angle. By way of contrast, elephants tend to shred the edges of branches when they browse.

Black Rhinos often feed on burnt plants and recoppicing browse in burnt areas (Mukinya 1977, Emslie 1999, P. du Preez pers. comm.), preferring areas with intermediate intensity burns (Emslie 1999). Increasing attention is being paid to the negative impact that other potentially competing browsers may have or have had on Black Rhino habitats and carrying capacities (Kuria 1995, Birkett 2002, Walpole *et al.* 2004).

Social and Reproductive Behaviour Black Rhinos tend to be solitary animals, although ♀♀ are less solitary than ♂♂, as they are usually associated with one or more of their immature or subadult offspring. Adults spend most of their time and do most of their feeding within defined home-ranges. Mature adult home-ranges tend to be stable in location for several years (Adcock *et al.* 1998). However, in establishing Black Rhino populations, ranges may shift over time (Lent & Fike 2003). The ranges of subadult and young adult animals are not stable and tend to be larger than those of most mature adults (Adcock *et al.* 1998). The log of average adult male Black Rhino home-range size in an area is inversely proportional to the log of Black Rhino carrying capacity of an area, as predicted by regression modelling (Adcock 2001), even though individual rhino home-range sizes vary greatly (Adcock 2001; and see, for example, Hitchins 1969, Mukinya 1973, Frame 1980, Conway & Goodman 1989). Thus, in very arid areas of low rhino carrying capacity, such as 0.01 rhino/km², ranges average around 380 km² (Hearn 1999). Areas that can carry ten times more rhinos (0.1 rhino/km²) tend to have ranges averaging 43–44 km²; while areas that can carry 1 rhino/km² tend to have ranges averaging around 5 km².

Male territoriality has been shown in all areas where the actual ages and range layouts of the ♂♂ have been monitored (Klingel & Klingel 1966c, Frame 1980, Adcock 1998, Tatman *et al.* 2000, Lent & Fike 2003). Mature adult ♂♂ usually show territorial behaviour in that a single 'dominant' bull resides in a specific range, which overlaps little with the ranges of other bulls of a similar status. Such a bull is usually a mature adult well over ten years old. Other 'subordinate' bulls, which are usually subadults or younger adults, are tolerated within a dominant bull's range until they start to display challenging or territorial behaviour. Social dominance seems to be achieved between the ages of 9 and 17, some years after sexual maturity is reached at 7–8 years of age.

A dominant bull will aggressively chase a non-tolerated ♂ from his territory. Young bulls are often killed or injured in these interactions.

Black Rhinoceros *Diceros bicornis*.

Dispelled bulls must lead a fringe existence in unoccupied areas, or must wander continuously to avoid dominant bulls, until they can find or claim their own territory. Old ♂♂ that can no longer defend their territories also die in fights, or can become confined to a small area of marginal habitat until they die. Dominant bulls are predominantly solitary, but younger, subordinate ♂♂ may associate with each other or with adult ♀♀ on occasion. Male territoriality limits the number of mature ♂♂ that can co-exist in fenced rhino sanctuaries (Adcock 1994, 1998).

There is some evidence that overt territorial behaviour can be suspended around specific important, but limited, resources, where rhinos can gather in groups of five or more. Examples include around waterholes in arid ecosystems (e.g. aggregations of up to 16 individuals in Etosha N. P. in Namibia; Cunningham & Berger 1997, B. Loutit pers. comm.), or around prized resources such as succulent euphorbias (e.g. Dwarf Succulent Valley Bushveld habitat in South Africa; Lent & Fike 2003), and, formerly, in patches of deciduous thicket (made up of *Combretum*, *Grewia*, *Baphia*, *Burttia*, *Pseudoprosopis* and *Albizia* spp.) in Uzigua and Manyoni districts of Tanzania (J. Kingdon pers. comm.). They also aggregate over such resources when artificially confined, as in Ngulia Sanctuary in Tsavo West, Kenya (R. Ketch pers. comm.) and in *Euphorbia* forests in Lake Nakuru N. P. (P. Okuku pers. comm.). Females occupy home-ranges that can overlap those of other ♀♀ and ♂♂. Meetings between different adult ♀♀ (and associated calves) are peaceful. Encounters are sometimes deliberately sought if rhinos detect each other when moving through a common area, but these invariably are of a temporary nature.

Black Rhinos use olfactory communication, including scent-marking by dung scattering and urine spraying. Dung middens are scattered seemingly at random along paths and used by all passers-by. Black Rhinos often defecate on White Rhino territorial dung middens where the two species coexist. The depositor of dung may sniff it and may sweep and root it with the forehorn (especially ♂♂) before shuffling through it with stiff legs (Estes 1991). Black Rhinos scatter their dung by kicking backwards in slow motion, leaving characteristic parallel scrapes. Females in oestrus dump whitish urine, which advertises their status to ♂♂ who test this with flehmen behaviour. Bulls also spray-urinate on small bushes (Estes 1991).

When an oestrous ♀ moves into a ♂'s territory, the resident ♂ rhino will court her and mating may ensue. Courting can be a lengthy affair. This involves the ♂ engaging in stiff-legged walking, some jousting of horns with the ♀, and restrained jabbing of his horn under her groin, front legs or belly. Females may attack courting ♂♂ on occasion. Actual copulation may last 12–43 min (Goddard 1966, Hitchins & Anderson 1983).

Related rhinos tend to maintain long-term bonds and often join up with each for short periods over their lifetime. In East Africa, such groups (clans) of related rhinos have been found to occur in particular 'distribution areas', which show little or no overlap with the distribution areas of other such groups (Mukinya 1973, Morgan-Davies 1996, Tatman *et al.* 2000).

Young ♀♀ can wander widely before they produce their first calf. They then settle into a more established home-range that may or may not coincide with that of their mother. Pregnant ♀♀ have been known to return temporarily to their own birth area when they are due to give birth (H. Hansen pers. comm.). As the time for parturition

approaches, the ♀ will chase her previous calf away, and will find a secluded bushy area to give birth in. Females sometimes hide their infant calves when they go to waterholes (P. Erb pers. comm.) or when feeding in exposed areas. Newborn calves walk and suckle within hours of birth. The older, rejected calves (aged 2–3½ years) at this stage become more vulnerable to predation, aggression by ♂ rhinos, and other mishaps. They appear to be insecure on their own, and usually attempt to join another ♀ or occasionally young ♂, or even a White Rhino ♀ who will tolerate their presence. After 3–8 months, the mother may allow her former calves to return to her company. Calves start to break ties with their mother from 2–3½ years on, but ♂ calves in particular may not truly leave their mothers permanently until they are six or seven years.

The explosive puffing snort of an alarmed Black Rhino can precede a dangerous charge, but more often Black Rhinos run away from perceived threats. A calf emits a high-pitched whine or squeal to attract its mother's attention. A ♂ may also squeal when courting a ♀, and all Black Rhinos can make this sound when in pain or distress.

Black Rhinos are often found in association with Fork-tailed Drongos *Dicrurus adsimilis*, which hawk insects by flying along the sides of resting rhinos, and with oxpeckers, which feed on ticks and skin secretions. The birds also give a harsh alarm call, which has led to oxpeckers being called *askari ya faru*, or the 'rhino's policemen' in Swahili.

Reproduction and Population Structure Fertility depends to some extent on body condition and weight. Animals can become sexually mature in their fourth or fifth year if they can achieve 80% of their adult body weight by this stage. Most ♀♀ achieve sexual maturity during their sixth year, resulting in average ages at first calving of 7–8 years (though some breed earlier). Males seem to commonly achieve sexual maturity (spermatogenesis) at an older age of 7–8 years (Hitchins & Anderson 1983, Bertschinger 1994). Fertility can be delayed in both sexes due to nutritional stress, or social pressures in the case of young ♂♂.

Oestrous cycles have a mean of 35 days, but true oestrus only occurs for one or two days during each cycle (Hindle *et al.* 1992, Bertschinger 1994). Cycling can occur year-round, but is influenced by ♀ nutritional status. Several populations have shown conception peaks at times of the year that correspond to improved rainfall conditions, and thus nutritional status of the ♀ in the months preceding conception (Adcock 2000, 2003). The timing of these peaks varies across Africa with the seasonality (winter versus summer) of the annual rainfall pattern.

Gestation period is 15.4 months and calves weigh 25–40 kg at birth (Penny 1987, Bertschinger 1994). The calving interval varies widely, depending on the age of the ♀ and the nutritional conditions in the habitat. Under good habitat conditions and at densities below carrying capacity most ♀♀ can produce several consecutive calves at 2–2.5 year intervals. Where conditions are less favourable, the average inter-calving interval exceeds three years. In many such cases, a calf may be conceived but is lost as the pregnancy nears full term, or shortly after birth. Old ♀♀ (28 years plus) have difficulty regaining body condition after weaning each calf, and tend to have longer intervals between calves.

Mortality rates within the first year of life range from 8–14% on average in South Africa and Namibia. Mortality in subadults averages

2–4%, less than 2% in young and prime age adults (Adcock 2003), and probably 4% or more in older rhinos. Male rhinos have a higher mortality rate than ♀♀, and fighting is the most common cause of their death. Most ♀♀ die of old age. Longevity for *D. b. michaeli* in captivity has been given as 45 years and 10 months (Jones 1993).

More male calves are born than female calves (Adcock *et al.* 2010), but male mortality rate is higher leading to adult sex ratios biased towards ♀♀. Because of male territoriality limiting male numbers in all but the largest fenced areas, adult sex ratios tend to average 1.3–1.5 ♀♀ per ♂ in many populations. Larger populations have average sex ratios of 1.1–1.2 ♀♀ per ♂.

The intrinsic rate of increase in Black Rhinos is around 8–9% annually (Owen-Smith 1988, 2001, Emslie 1999), similar to White Rhinos (although in practice breeding rates of the browsing Black Rhino lag behind those of the grazing White Rhino). In areas that have been stocked with rhinos at below their habitat carrying capacity, and having ♀-biased sex ratios and low mortality rates, they can commonly achieve average population growth rates of 10–15% per year. In populations approaching carrying capacity, overall mortality can exceed 4% annually (involving mainly infants and subadults), and inter-calving intervals lengthen. This results in average growth rates of zero or a few per cent (Adcock 2003). Black Rhino populations that have been allowed to approach or exceed estimated long-term ecological carrying capacity have consistently exhibited declines in population. Vegetation changes and increases in the density of competing browsers, as well as fluctuating rainfall, also will affect performance.

Predators, Parasites and Diseases Calves and subadults are vulnerable to predation by Lions *Panthera leo*, Leopards *Panthera pardus* and Spotted Hyaenas *Crocuta crocuta* (e.g. Goddard 1966, Joubert & Eloff 1970, Elliot 1987, Scott & Scott 2003). Brain *et al.* (1999) reported on the killing of three subadult Black Rhinos by a coalition of three male Lions in Etosha N. P. within the space of a few months; the three rhinos killed were of very similar size (1.27–1.31 m at the shoulder) and age (3–4 years) and the authors suggested that subadult rhinos that have just left their mothers may be particularly susceptible to Lion predation. In N Tanzania, Goddard (1966) estimated that there was a 16% loss of calves less than two years old to Lion and Spotted Hyaena predation.

In contrast to White Rhinos, a Black Rhino calf tends to follow rather than precede its mother when running away from danger. This behaviour is thought to make this species more vulnerable to predation. However, upon hearing alarm squeals of her calf, a Black Rhino mother will turn to defend her calf. Calves less than three months old appear to be at greatest risk from predation.

Black Rhino numbers have increased rapidly in many populations with a full complement of predators, and it appears that, while some young and subadult animals are undoubtedly lost to predation, rhinos stocked at sustainable carrying capacities can withstand predation. Thus, predators are not generally a major influence on population performance in most populations. An exception to this is in the Ngorongoro Crater, where Spotted Hyaena densities have been very high while Black Rhino densities have become very low through poaching, and the terrain has become open with limited bushy areas for cows to hide calves. Mortality of Black Rhinos in their first year of life here is more than 30% (Adcock *et al.* 2004, Emslie 2004b). If

one assumes inter-calving intervals in excess of four years represent undetected neonatal mortalities, neonatal mortality of Black Rhinos in the Crater may have been as high as 41–47% (Adcock *et al.* 2004, Emslie 2004b, Mills *et al.* 2006).

Southern African Development Community Rhino Management Group data since 1989 indicate that the proportion of detected mortalities in populations in areas with large predators that were ascribed to predation was 6.9%, with suspected Lion predation accounting for 13 of 16 predator-linked mortalities out of a total sample size of 233 mortalities (SADC RMG data – K. Adcock unpubl.). Lion predation may be overestimated, as in some cases, lions may have simply discovered a Black Rhino carcass and scavenged from it rather than killing it. Similarly, Spotted Hyaena predation levels are likely to be underestimated from recorded mortality data as little evidence may remain if a very young calf is killed and eaten in the bush.

Aggressive encounters with Savanna Elephants *Loxodonta africana* and African Buffalo *Syncerus caffer* have also been recorded. In 159 encounters between elephants and Black Rhinos in Etosha, ♀ elephants dominated both sexes of Black Rhino, while Black Rhino ♂♂, though not ♀♀, were capable of displacing elephant bulls (Berger & Cunningham 1998). Some Black Rhinos have been killed by young bull elephants in some populations where elephants were re-introduced using young orphaned animals from culls rather than family groups with big mature adult elephant bulls (Slotow *et al.* 2001). To date, many more White Rhinos have been killed by these juvenile, bull delinquents than Black Rhinos. Only 2.1% (5/233) recorded Black Rhino deaths in the SADC RMG region since 1989 have been ascribed to elephants (SADC RMG data – K. Adcock unpubl.). It is still too early to conclude with certainty, but the introduction of large adult bulls into populations such as Pilanesberg and Hluhluwe–iMfolozi appears to have reduced mortality.

Black Rhinos are susceptible to trypanosomiasis, and *Trypanosoma brucei*, *T. congolense* and *T. vivax* have been reported from Black Rhinos (Penzhorn *et al.* 1994). Black Rhinos translocated from non-trypanosomiasis areas to trypanosomiasis areas are at risk until they build up immunity. Translocation mortality risks can be reduced with good boma care and setting up Tsetse Fly traps in the area surrounding holding bomas to reduce fly densities and give the animals time to build up immunity (Wambwa 2004).

Anthrax has killed the occasional animal, but at a continental scale its impact has been limited. Since 1989 only two Black Rhinos have been recorded as dying from anthrax in the SADC RMG region (0.9% of all recorded deaths since 1989). In total, including cancer and anthrax, disease accounted for 3.4% (eight) of all recorded mortalities in parks with large predators (n = 233; SADC RMG data – K. Adcock unpubl.).

A total of 35–38 tick species have been recovered from Black Rhinos (see Penzhorn *et al.* 1994 for checklist), of which three tick species are primarily rhino parasites: *Amblyomma rhinocerotis*, *Dermacentor rhinocrinus* and *Amblyomma personatum* (Penzhorn *et al.* 1994; and see Knapp *et al.* 1997). Common sites of tick attachment are skin folds in the perineal region, in and around the ears and around the eyes (Penzhorn *et al.* 1994). Oxpeckers and terrapins in wallows assist rhinos by eating ticks. Rhinos also wallow in mud and then rub themselves on special rubbing posts, trees and rocks in an attempt to remove ticks on their skin. *Babesia* and *Theileria*

like organisms have been found in healthy White Rhinos (Bigalke *et al.* 1970); however, deaths of a small number of Black Rhinos in Ngorongoro and Addo Elephant N. P. have been linked to tick-borne diseases caused by protozoan parasites identified as *Babesia bicornis* and *Theileiria bicornis*. In these cases it is believed that general stress associated with translocation and drought-induced malnutrition, and a build up of ticks following a lack of burning were key factors predisposing these animals to succumb to babesiosis (Hilsberg *et al.* 2003, Adcock *et al.* 2004, Mills *et al.* 2006). Aspergillosis is another example of a latent infection/disease that can be exacerbated by translocation stress (Kock & Miller 2004).

Large swarms of the large blood-sucking fly *Rhinomusca dutoiti* and *R. brucei* are often seen along the sides of Black Rhinos. Birds such as oxpeckers and drongos *Dicrurus* spp. often hawk these flies. These flies lay their eggs in rhino dung middens where their larvae develop. Much smaller flies of the genus *Lyperosia* are also commonly associated with rhinos and their middens. Large numbers of gyrostigmatid (bot) fly larvae (*Gyrostigma pavesii* and *G. conjungens*), up to 40 mm long, may be found attached to the stomach walls of rhinos. At least 30 species of helminths (see Penzhorn *et al.* 1994 for a checklist) are known to parasitize the Black Rhino. Ciliated intestinal protozoa are reported on by Van Hoven *et al.* (1988) and Obanda *et al.* (2008).

In some areas, such as in KwaZulu–Natal (Schulz & Kluge 1960, Hitchins & Keep 1970) and parts of Kenya (Round 1964, Tremlett 1964) and Zimbabwe (Kock & Kock 1990), Black Rhinos can develop characteristic large skin lesions on their chests and shoulders due to a filarial parasitic worm. Where this parasite is absent, these lesions do not develop. As the positions and size of the lesions change with a rhino's age, over time and with season (Hitchins & Keep 1970), they are not useful features for identifying individual animals (Adcock & Emslie 2004).

Black Rhinos have unusual blood chemistry as their red blood cells are sensitive to oxidative stress. This has predisposed this species to high mortality rates in captivity. Captive Black Rhinos have suffered from a wide range of conditions (Wambwa 2004), including acute episodic haemolytic anaemia, chronic haemolytic anaemia, superficial necrolytic dermatopathy, haemosiderosis, idiopathic and toxic hepatopathies, a susceptibility to fungal pneumonias and other infectious agents, and other incompletely understood disorders (Miller 1992, 1994, Munson *et al.* 1998). These conditions are seldom if ever seen in the wild (Wambwa 2004). Attempts are being made to improve captive diets in an attempt to prevent a build up of iron in captive animals and reduce mortality levels in captivity.

Conservation IUCN Category: Critically Endangered A2abdc (*D. b. minor* – Critically Endangered A2abdc; *D. b. bicornis* – Vulnerable D1; *D. b. michaeli* – Critically Endangered A2abdc; *D. b. longipes* – Extinct). CITES: Appendix I.

The population of Black Rhinos has declined by over 90% over the last sixty-odd years, reaching a low of 2410 in 1995 (Emslie & Brooks 1999). However, since then, numbers have been increasing steadily at a continental level, doubling to 4880 by the end of 2010 (Emslie 2011). For the most part, the large free-ranging populations of rhinos that used to roam over huge areas, and which could not be adequately protected, have been eliminated or reduced to very low

numbers. The bulk of remaining Black Rhinos occur in areas with more concentrated security. However, following surveys over most of its possible range in 2006, the Western Black Rhino in Cameroon has been declared extinct as no signs of any individuals were found by survey teams in 2006 or in the following five years, while evidence of general wildlife poaching was widespread (Emslie *et al.* 2007).

Black Rhinos are found under a range of management and ownership models. In 2010, 71.2% of Africa's Black Rhinos were conserved in state-run protected areas. The bulk of privately managed Black Rhinos in 2010 were under custodianship on behalf of the state (19.9% of all Black Rhinos) with 6.8% being privately owned (AfRSG data unpubl.). This differs from White Rhinos, where, in 2010, 27.3% were privately owned. Approximately 3.2% of Africa's Black Rhinos are conserved on communally owned and managed land. In summary, as of December 2010, there were 17 strongholds of the species with over 50 animals (up from 11 in 1995), including Etosha N. P., Kunene, Hluhluwe–iMfolozi N. P., Kruger N. P., Great Fish Reserve, Nairobi N. P., Lake Nakuru N. P., Pilanesberg N. P., uMkhuze G. R., an intensive protection zone in Hwange N. P., and three Zimbabwean conservancies, three privately managed Kenyan areas and two privately owned South African populations (Emslie 2011).

For practical conservation management, current Continental, Regional and National Black Rhino Conservation Plans all stipulate that the different subspecies of Black Rhino should not be mixed (unless major declines in numbers and loss of genetic variability in future dictates otherwise). See also Taxonomy.

As with White Rhinos, the primary threat remains the high price of rhino horn (Leader-Williams 1988) and the resultant poaching for the illegal international rhino horn trade. Rhino horn has two main uses: traditional use in Chinese medicine, and for making ornately carved handles for ceremonial daggers (Jambiyas) worn in some Middle East countries (Martin & Martin 1982). Since the 1960s wars, the free flow of weapons into Africa, civil unrest, poverty, economic problems and declining conservation budgets have had a significant impact on rhino numbers in many countries (Emslie & Brooks 1999). Habitat changes and increasing densities of competing species can also cause rhino populations to decline, while poor (conservative) biological management also threatens rhino growth rates. Maintaining sufficient capacity and resources to do effective field rhino conservation is a challenge. In Zimbabwe, for example, where Black Rhino numbers (but not White Rhinos) declined slightly (–1.7 %) between December 2003 and December 2005, significant field conservation effort (i.e. protection and translocations to maintain productivity of established populations and create additional populations), coupled with political will, have been the primary reasons for continued successes (Emslie *et al.* 2007).

The Black Rhino has been listed on CITES Appendix I since 1977, with all international commercial trade in Black Rhino and their products prohibited. To help reduce illegal trade, and complement CITES international trade bans, domestic anti-trade measures and legislation were implemented in the 1990s by a number of consumer states. However, live breeding groups of Black Rhino have been translocated between countries to help re-establish populations in a number of range states. At the 13th CITES Conference of the Parties in 2004, proposals for hunting quotas for five surplus male Black

Rhino were also approved for both Namibia and South Africa (for more details on the rationale behind these hunting proposals and the debate at CITES CoP 13, see Emslie 2004c).

Strategies that have been central to increasing numbers include monitoring and managing rhinos on a metapopulation basis for rapid growth (Emslie 2001), and concentrating law enforcement effort at levels where it can be effective (Leader-Williams *et al.* 1990, Emslie & Brooks 1999). Work is currently ongoing to study the social impacts of translocations with a view to developing improved biological management and translocation guidelines (W. Linklater pers. comm.).

Measurements

Diceros bicornis

HB: 2900–3750 mm

T: 600–700 mm

HF: n. d.

E: n. d.

Sh, ht: 1370–1800 mm

WT: 700–1400 kg

Kingdon 1997; sample number not given

Notes: The mean mass of a small sample of Black Rhinos from Hluhluwe G.R., KwaZulu–Natal was 852 kg for ♂♂ (n = 8) and 884 kg for ♀♀ (n = 6) (Hitchins 1968). Du Toit (2005) also gives a slightly lower average mass at maturity for ♂♂ of 852 kg (700–1020 kg) compared with ♀♀ 880 kg (720–1130 kg). Estes (1991), on the other hand, describes ♀♀ as large as ♂♂, but ± 100 kg lighter. Mature adult ♂♂ develop visibly bigger neck muscles, and some ♂♂ are obviously big animals and are likely to be the heaviest animals (J. Flamand pers. comm.); however, a pregnant ♀ normally weighs as much as the average ♂ (Q. Rochat pers. comm.). The heavier mean for ♀♀ in some references may be due to the inclusion of a number of

animals in late pregnancy. Four ♀♀ and four ♂♂ (*D. b. minor*) over 6/7 years of age had average weights of 1020 kg (range 972–1149 kg) and 1164 kg (range 1044–1228 kg), respectively. Q. Rochat (pers. comm.) concurs with statements there is not too much difference in weight between sexes and that some ♀♀ are bigger than some ♂♂. None the less, the largest animals are very big bulls. These latter figures, taken from rhinos weighed in crates using a crane with an electronic scale (accurate to 5 kg), are also higher than previously reported, possibly due to more accurate weighing or because other weights were derived from younger animals being translocated.

Average mass per individual (subspecies not specified) in an entire population is 818 kg (Bothma & Van Rooyen 1990). Du Toit (2005) gives a mean mass for *D. b. minor* of 852 kg but notes that *D. b. bicornis* is larger with adult bulls weighing up to 1300 kg.

Horn measurements:

Diceros bicornis

Anterior basal circumference (♂♂): 492.7 ± 69.5 mm, n = 58

Anterior basal circumference (♀♀): 453.5 ± 44.2 mm, n = 38

Anterior horn length (♂♂): 446.1 ± 101.2 mm, n = 63

Anterior horn length (♀♀): 417.6 ± 107.9 mm, n = 49

Anterior horn WT (unsexed): 1.7 ± 0.7 (0.2–3.8) kg, n = 75

Posterior horn WT (unsexed): 0.9 ± 0.5 (0.02–2.4) kg, n = 74

Kruger N.P. and KwaZulu–Natal, South Africa (Pienaar *et al.* 1991, Pienaar 1993)

Note: The maximum front horn length is 1359 mm from Kenya (Selous 1899)

Richard H. Emslie & Keryn Adcock

Glossary

abbrev. = abbreviation

adj. = adjective

cf. = *confer*, compare with; as opposed to

Lat. = Latin

n. = noun

pl. = plural

q.v. = *quod vide*, 'which see'

v. = verb

acetabulum: the concave socket (fossa) in the pelvic bone in which the head of the femur articulates.

acrocentric: describes a chromosome that has the centromere (*q.v.*) very near one end and that therefore appears to have only one arm (= telocentric (*q.v.*) for practical purposes).

ad libitum: (*Lat.*) as much as one likes; having unrestricted access to a resource (e.g. water or food).

aestivate: state of torpor (*q.v.*) induced by cold or drought; usually associated with a reduced metabolic rate and inactivity.

aFN: the total number of chromosomal arms in the autosomal chromosome complement of a species (*cf.* fundamental number [FN], which includes the chromosomal arms of the sex chromosomes as well as those of the autosomal (*q.v.*) chromosomes). Each metacentric (*q.v.*), submetacentric (*q.v.*) or subtelocentric (*q.v.*) chromosome is given a value of 2; each acrocentric (*q.v.*) chromosome is given a value of 1. *See also* fundamental number.

afroalpine: describes habitats and/or vegetation occurring above the treeline on African mountains. Includes montane grassland and heathlands.

afromontane: refers to mountainous regions in Africa, e.g. afromontane forests and afromontane grasslands.

agouti: having an even mixture of pale- and dark-tipped hairs on the pelage creating a grizzled, speckled or 'pepper and salt' appearance.

Albertine Rift Valley: *see* Rift Valley (*q.v.*).

alisphenoid: bone in the skull.

Allee effect: a scenario in which populations at low numbers are affected by a positive relationship between population growth rate and density, which increases their likelihood of extinction.

allele: an alternative form of a gene. A diploid organism carries two alleles (which may be same or different) for each gene locus. At any one locus, there may be several possible alleles (although only two are present in a single organism).

Allelomimetic behaviour: behaviour in social animals in which each animal does the same thing as those nearby.

Allen's Rule: A rule that states that structures in endotherms such as limbs (which are more prone to heat loss) are reduced in size by means of natural selection over time in cooler climates (to reduce heat loss).

allogrooming: grooming behaviour directed at another individual. *cf.* autogroom (*q.v.*).

allomothering: non-parental mothering; caring for young by individuals (male or female) that are not the parents of the young.

allopatry (*adj.* **allopatric**): the situation where populations of the same or different species have non-overlapping geographic ranges; refers also to populations of the same, or different, species that are geographically separated. *cf.* sympatry (*q.v.*); syntopy (*q.v.*).

allozyme: one of a number of forms of the same enzyme having different electrophoretic properties and that are encoded by alternate alleles at the same genetic locus.

altimontane: collective term for the belts of ericaceous and afroalpine vegetation on the high mountains of tropical East Africa (White 1983).

altricial: describes young born in an undeveloped state. *cf.* precocious (*q.v.*).

altruism: behaviour that enhances the reproductive and genetic fitness of another individual at the expense of its own.

alveolus (*pl.* **alveoli**, *adj.* **alveolar**): small cavity; socket that houses the root of a tooth.

angular process: process at the posterior lower corner of the mandible; situated ventral to the coronoid process (*q.v.*).

ante-orbital (= **anteorbital**): in front of the orbit (*q.v.*).

antebrachial: anterior to the arm (forelimb).

anterior palatal foramina: the two foramina (*q.v.*) on the ventral part of the skull.

apomorphy (*adj.* **apomorphic**): situation in which a novel character evolves from a pre-existing character. In cladistics (*q.v.*), an apomorphic character shared among two or more species (synapomorphy [*q.v.*]) indicates shared descent from a common ancestor and hence monophyly (*q.v.*). *cf.* plesiomorphy (*q.v.*).

arboreal: living above the ground (in trees and shrubs). *cf.* scansorial (*q.v.*); terrestrial (*q.v.*).

auditory bulla: *see* tympanic bulla.

auditory meatus (*pl.* **auditory meati**): the external opening of the ear; the passage leading from the tympanic membrane (ear drum) to the external ear.

autapomorphy: derived trait uniquely characteristic of a taxon.

autogroom: grooming behaviour in which an individual grooms itself. *cf.* allogroom (*q.v.*).

autosomal: pertaining to any chromosome other than the sex chromosomes.

bachelor herd: a herd comprised entirely of males, usually mature, but of mixed age.

baculum (*pl.* **bacula**, *adj.* **bacular**): the os penis, or penis bone, which supports the penis in some mammals.

bai (*pl.* **bais**): an opening or clearing.

basal metabolic rate: metabolic rate required for survival in the thermal neutral zone (*q.v.*); a state that requires the lowest expenditure of energy when at rest.

basicranium: the base of the skull.

- basisphenoid**: cranial bone in middle of base of skull; the median posterior part of the sphenoid bone, forming part of the floor of the braincase.
- Bergmann's Rule**: The theory that the size of a warm-blooded animal in a single, closely related, evolutionary line, increases along a gradient from warm to cold temperatures.
- bicuspid**: having two points or cusps (particularly of teeth).
- bifid**: divided by a shallow notch.
- bilophodont**: describes cheekteeth having two transverse ridges.
- bipedal**: body supported by the two hindlimbs; movement not using the forelimbs.
- blastula**: a hollow ball of undifferentiated cells (derived from a fertilized ovum by cell division), which represents one of the earliest stages of embryonic development.
- BP**: (*abbrev.*) before the present.
- brachydont**: describes a premolar or molar tooth with low crowns. *cf.* hypsodont (*q.v.*).
- braincase (= cranium)**: that part of the skull housing the brain; the part of the skull posterior to the front line of the orbits. *cf.* rostrum (*q.v.*).
- buccal**: On the cheek side of the mouth or teeth or penetrating to the cheek or sometimes used broadly as pertaining to the cavity of the mouth.
- bullae**: *see* tympanic bulla.
- bunodont**: describes molar teeth, entirely covered by enamel, that have low, rounded, hill-like cusps (as opposed to sharp, pointed cusps). (*cf.* hypsodont, lophodont).
- bushmeat**: meat for human consumption derived from non-domesticated mammals, birds and reptiles taken from their natural habitats and domiciles.
- bushveld**: savanna vegetation type characterized by a grassy ground layer and a moderately dense upper layer of shrubs and scattered trees.
- BZ**: (*abbrev.*) Biotic Zone.
- C or c**: (*abbrev.*) canine tooth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* canine.
- c.u.**: (*abbrev.*) (*Lat. cum unguis* = with nail) measurement of the hindfoot when length of the nail on the claw is included in the measurement. Usually hindfoot is measured without the claw because claws may be broken or worn. When length of claw is included, it is conventional to record as 'HF c.u.'. *cf.* s.u. (*q.v.*)
- caecum (pl. caeca)**: a blind-ending pouch in the alimentary canal (often enlarged as a fermentation chamber) located at the junction of the small and large intestines.
- canine**: the most anterior tooth on the maxilla bone and in a similar position on the mandible; situated immediately posterior to the incisors; if incisors are absent, the most anterior tooth in the jaw. Unicuspid; tall and pointed in most mammals. Never more than one canine on each side of each upper and lower jaw; absent in some taxa.
- caniniform**: having shape and appearance of a canine tooth.
- carnassial shear**: Found in some carnivores and formed by the blade-like cusps of the fourth upper premolar teeth and first lower molar teeth, which, occluding together like the blades of a pair of scissors, provide a shearing action for cutting through tough skin or bone. Sometimes referred to as the carnassials.
- carotid**: pertaining to the carotid artery located in the front of the neck through which blood from the heart flows to the brain.
- cauda epididymides**: the ducts of the epididymides at the posterior end of the testes that carry sperm from the testes to the vas deferens, which, in turn, carries sperm to the penis. Sometimes used to store sperm prior to copulation.
- caudal**: pertaining to the tail; in the direction of the tail.
- Cenozoic (= Cenozoic Era)**: geological era, ca. 65 mya to today, comprising the Quaternary and Tertiary Periods: the Age of Mammals.
- central Africa**: Cameroon (south of the Sanaga R.), Central African Republic (but only south of ca. 7° N), Equatorial Guinea, Gabon, DR Congo (except SE). Mainly rainforest habitats and rainforest-savanna mosaics.
- centromere**: the part of a chromosome where sister chromatids are linked together during mitosis.
- cerebellum**: the part of the hindbrain that controls and coordinates motor movements, posture, balance and muscle tone.
- cerebrum (= cerebral hemispheres)**: the anterior part of the brain that is involved in voluntary movements, processing sensory information, olfaction, learning, memory, communication and other functions.
- cervical**: pertaining to the neck.
- cf.** (in general usage): compare or compare with. In the context of descriptions, implies a difference or contrast: e.g. 'In *Elephantulus edwardii*, first lower premolar single-rooted (*cf.* *E. myurus* in which the first lower premolar is double-rooted).'
- cf.** (in taxonomy): precedes the specific name if there is uncertainty in the assignment.
- cheekteeth**: the premolar (*q.v.*) and molar (*q.v.*) teeth combined.
- choana (pl. choanae)**: the openings of the internal nostrils on the skull, situated immediately posterior to the bony palate.
- chromosome**: one of the thread-like bodies within the nucleus of a cell, which carry the genes (genetic material) in linear order; each chromosome is composed of one long molecule of DNA (and two long molecules at cell division). Chromosomes occur in pairs (one from each parent) and are visible as rod-like bodies in cells that are dividing. The total number of chromosomes in a cell is expressed as the diploid number (2n).
- CI**: condyloincisive length; the length of the skull from the anterior end of the longest incisor tooth to the posterior end of the occipital condyles. *cf.* GLS.
- cingulum (pl. cingula)**: ridge around the base of the crown of a tooth.
- CITES (abbrev.)**: Convention on International Trade of Endangered Species of Wild Fauna and Flora; an international treaty set up to ensure that international trade in wild animals and plants does not threaten the survival of species in the wild. It accords varying degrees of protection to more than 33,000 species of animals and plants. Appendix I lists species that are the most endangered among CITES-listed animals and plants. Appendix II lists species that are not necessarily now threatened with extinction but that may become so unless trade is closely controlled. Appendix III is a list of species included at the request of a Party that already regulates trade in the species and that needs the cooperation of other countries to prevent unsustainable or illegal exploitation.

- clade:** branch of a phylogenetic tree containing the set of all organisms descended from a common ancestor.
- cladistic (analysis):** a methodology that provides a classification in which organisms are grouped in terms of the time when they had a common ancestor.
- cline** (*adj.* **clinal**): in context of geographic variation, a gradual and sequential change of a character(s) without a significant break such as would justify division into separate subspecies or species.
- CMS:** Convention on Migratory Species of Wild Animals (also known as the Bonn Convention). An intergovernmental treaty, concluded under the aegis of the United Nations Environment Programme, concerned with the conservation of migratory terrestrial, aquatic and avian migratory species throughout their range. Migratory species threatened with extinction are listed on Appendix I; Migratory species that need or would significantly benefit from international co-operation are listed in Appendix II.
- CNL:** condylo-nasal length; measurement from the most anterior part of the nasal bone to the most posterior part of the occipital condyle (exoccipital) on the same side of the skull; a similar measurement to 'greatest length of skull'.
- cochlea** (*pl.* **cochleae**, *adj.* **cochlear**): a hollow structure, spirally coiled like a snail's shell, situated in the skull and containing the internal organ of hearing.
- competitive exclusion:** the principle that two different species cannot indefinitely occupy the same ecological niche.
- concatenation:** a chain of linked elements.
- concave:** having a curvature that curves inwards; having an outline or a surface curved like the interior of a circle or sphere. *cf.* convex (*q.v.*).
- concavity:** a concave depression in an outline or surface.
- conceptus:** embryo prior to implantation.
- conductance:** in thermal biology, the rate at which heat passes across a temperature gradient, e.g. the density and thickness of the pelage affects the rate at which body heat passes from the body to the outside. Thick pelage, which traps and holds air, results in low thermal conductance.
- condylar process:** process at the posterior upper corner of the mandible, which forms the lower hinge of the jaw articulation; fits into the glenoid fossa (*q.v.*) of the skull.
- condylarth** (*adj.*): as in the Condylarthra, an extinct order of mammals.
- condyle:** a rounded process on a bone that articulates with a socket-like concavity in another bone.
- condylobasal length:** the length of a skull, measured from the anterior points of the premaxilla (*q.v.*) to the posterior surfaces of the occipital condyles (*q.v.*).
- congeneric:** belonging to the same genus.
- conspecific:** belonging the same species. *cf.* heterospecific (*q.v.*).
- contiguous:** touching; sharing a boundary (as in geographic ranges).
- convex:** having a curvature that bulges outwards; having an outline or a surface curved like the exterior of a circle or sphere. *cf.* concave (*q.v.*).
- coprophagy:** the eating of faeces. Includes the eating of an individual's own faeces as they are voided from the anus.
- copulatory plug:** plug formed in the vagina of the female after copulation; formed from seminal fluids of the male. Prevents or reduces the chance of sperm from another male(s) entering the female reproductive tract if the female copulates again soon after copulation with the first male.
- coronoid canal:** a foramen (canal) in the coronoid process (*q.v.*) of the mandible.
- coronoid process:** angular pointed process on the upper margin of the mandible, situated anteriorly to the condylar process (*q.v.*); does not participate in the jaw articulation.
- corpus luteum** (*pl.* **corpora lutea**): a glandular mass of tissue on the surface of an ovary, that develops after the extrusion of an ovum from a Graafian follicle (*q.v.*); secretes the hormone progesterone.
- cotype:** originally synonymous with syntype but now used as synonym of paratype (*q.v.*).
- CR:** (*abbrev.*) *see* crown–rump length.
- cranial profile:** the shape of the cranium (the part of the skull that surrounds the brain) when viewed from the side.
- craniodental:** pertaining to the skull and teeth.
- cranium:** that part of the skull housing the brain. Also called braincase.
- crepuscular:** at, active in, twilight, when light intensity is higher than at night but lower than during the day. *cf.* diurnal (*q.v.*); nocturnal (*q.v.*).
- Cretaceous Period:** period (within the Mesozoic Era); 146–65 mya.
- crown:** (1) top of head; (2) exposed part of a tooth (visible above gum), especially the grinding surface.
- crown–rump length (CR):** distance from the crown of head to the rump of a foetus (i.e. maximum length of a foetus in its natural form).
- cuckolding:** when an intruding male mates with an oestrous female without her mate being aware of the event.
- cursorial:** pertaining to running.
- cuspidate** (*adj.* **cuspidate**): a prominence or sharp point, such as on the occlusal surface of some teeth. *See also* t.
- cutaneous:** (*adj.*) pertaining to the skin.
- Cyrenaica:** a region of North-East Libya. Includes the Cyrenaican Plateau and that part of the Mediterranean Coastal Biotic Zone between the plateau and the sea, as well as drier terrain south of the plateau.
- cytochrome b:** a protein involved in electron exchange in the mitochondria. It is the product of a gene in the mitochondrial genome. The sequence of this gene is often compared between species in phylogenetic studies to infer relatedness.
- cytogenetics** (*adj.* **cytogenetic**): the study of the microscopic structure of chromosomes, especially the mapping of genes.
- cytonuclear:** (*adj.*) pertaining to the nucleus and the cytoplasm of a cell.
- Dahomey Gap:** the geographic region where savanna habitat extends southwards to the West African coast in E Ghana, Togo, Benin (formerly Dahomey) and extreme SW Nigeria. The presence of savanna forms a break (or gap) in the extensive Rainforest Biotic Zone, which extends along the West Africa coast from Sierra Leone to Cameroon. The Dahomey Gap is an important biogeographical barrier separating the faunas to the east and west of the Gap.
- deciduous teeth:** *see* milk teeth (*q.v.*).

- Dega:** Ethiopian word for the temperate agricultural/economic altitudinal zone, about 2300–3000 m, warm enough for cereal-based agriculture.
- delayed implantation:** a means of lengthening the interval between copulation and parturition by delaying the implantation of the blastula (*q.v.*), so that both copulation and parturition can occur in the most optimal seasons. Development to blastula stage is followed by a period of halted development lasting several weeks or months; then the blastula implants and embryonic development proceeds normally, usually without any further interruption, until the young is born.
- deme:** a unit of population that is interbreeding and is separate from any other such population.
- dental formula:** a simple numerical method of denoting the number of incisor (I), canine (C), premolar (P) and molar (M) teeth on one side of the upper jaw and lower jaw, and the total number of teeth. For example, the dental formula of a primitive mammal is $I^{3/3}, C^{1/1}, P^{4/4}, M^{3/3} = 44$, which means there are three incisors, one canine, four premolars and three molars on each side of the upper jaw and also the lower jaw, making a total of 44 teeth. The formula may also be expressed in the form $^{3143}/_{3143} = 44$. Each incisor, premolar and molar is numbered according to its position in the tooth row; superscript numbers indicate upper jaw, subscript numbers indicate lower jaw (mandible) e.g. P^4 (upper fourth premolar), M_2 (lower second molar).
- dentine:** the substance, also known as ivory, comprising tusks (*q.v.*) and the interior hard part of vertebrate teeth. Lies under the enamel of teeth (but may be exposed if the enamel wears) and surrounds the pulp chamber and root canals.
- diastema:** space in the mouth between the incisor teeth and cheekteeth in those mammals that feed on grasses, herbs etc. (e.g. rodents, hares, rabbits, ruminants, etc.).
- dichromatism:** condition in which members of a species show one of only two distinct colours or colour-patterns.
- dilambdodont:** molar tooth with W-shaped ridges. *cf.* zalambdodont (*q.v.*).
- dimorphism:** *see* sexual dimorphism.
- diphyly:** the derivation of a taxon from two separate lines of descent. *cf.* monophyly (*q.v.*).
- diploid number (2n):** total number of chromosomes (including sex chromosomes) in a somatic cell of an organism.
- distal:** the end of any structure furthest away from the mid-line of the body or furthest from the point of its attachment. *cf.* proximal (*q.v.*).
- diurnal:** at, active in, daytime; when light intensity is high. *cf.* crepuscular (*q.v.*); nocturnal (*q.v.*).
- DNA hybridization:** technique of comparing the similarity between two DNA molecules by reassociating single strands from each molecule and determining the extent of double-helix formation. In phylogenetics, this technique is used to determine the relatedness of two or more taxa.
- DNA:** (*abbrev.*) deoxyribonucleic acid; the very large self-replicating molecule that carries the genetic information of a chromosome; each molecule is composed of two complementary chains of DNA.
- dorsoventral (dorsoventrally):** from dorsal to ventral surface; from back to belly of an animal.
- E:** (*abbrev.*) length of external (outer) ear (= pinna), measured from tip of ear to the posterior point of the ear conch). Length and shape usually affected by preservation.
- East Africa:** Kenya, Uganda, Rwanda, Burundi and Tanzania.
- eastern Africa:** SE Sudan, Ethiopia, Eritrea, Djibouti, Somalia, Kenya, Uganda, Tanzania, Malawi (but only south of L. Malawi and east of the Shire R. Valley) and Mozambique (but only east of Malawi and north of the Zambezi R.).
- echolocation:** the use of reflected ultrasonic pulses of sound to perceive the surroundings (including obstacles, prey and other animals).
- ecotype:** a genetically distinct geographic variety or population within a species, which is adapted to specific environmental conditions.
- ectoparasite:** a parasite that lives on the exterior of an organism (e.g. ticks, fleas, lice). *cf.* endoparasite (*q.v.*).
- ectotympanic:** a bony element within the middle ear that supports the tympanic membrane or eardrum.
- edaphic:** influenced by conditions of soil or substratum.
- emargination:** a distinct notch or indentation.
- embryo number:** number of foetuses within the uterus or uteri of the female (as assessed by autopsy). Expressed as mean number (with range from minimum to maximum, and sample size). *cf.* litter-size (*q.v.*).
- enamel:** hard material that forms a cap over the dentine component of a tooth; usually the most visible part of a tooth.
- encephalization quotient (EQ):** a measure of comparative brain size or weight defined as the ratio of the actual brain weight to the expected brain weight predicted for an animal of a given body weight.
- endemic:** restricted to, peculiar to, or prevailing in, a specified country or region.
- endoparasite:** a parasite that lives in the interior of an organism (e.g. nematodes, cestodes, blood parasites). *cf.* ectoparasite (*q.v.*).
- entoconid cusp:** the posterior cusp on the lingual (inner) side of a lower molar tooth.
- entotympanic:** an independent ossification found in the floor of the tympanic cavity in various extant and extinct eutherian groups, including, for example, Scandentia, Chiroptera, Dermoptera, Hyracoidea, Pholidota, Xenarthra, Carnivora, and Macroscelidea.
- Eocene:** geological Epoch (within the Tertiary Period); 55–38 mya.
- epiphysis (pl. epiphyses):** any part of a long bone that is formed from a different centre of ossification and that later fuses with the bone to form its terminal part.
- epitympanic recess:** a hollow located on the roof of the middle ear.
- erg:** a large, relatively flat area of desert covered with wind-swept sand with little or no vegetation cover (sometimes referred to as a dune sea).
- evaporative water loss:** the loss of water from the body through the skin and/or the lungs. A mechanism used by mammals to reduce T_b (*q.v.*) when T_a (*q.v.*) is high. Excessive evaporative water loss may lead to dehydration if free (drinking) water is unavailable.
- exfoliating:** shedding flakes (e.g. of bark), or breaking into relatively thin slabs (e.g. of granitic rock).
- exoccipital condyles:** a pair of projections from the occipital bone on either side of the foramen magnum (*q.v.*), which articulate with the first of the spinal vertebrae.

extant: living at the present time. *cf.* extinct.

F. R.: (*abbrev.*) Forest Reserve.

facultative: having the capacity to switch from one mode of life or action to another depending on conditions or circumstances. *cf.* obligate (*q.v.*).

female-defence polygyny: a mating system in which males control access to females directly, usually by virtue of female gregariousness (Emlen & Oring 1977).

fenestra (*pl.* **fenestrae**): opening in a bone, or between two bones.

flank: the side of the body of a mammal.

flehmen: an act performed by many species of mammals whereby an adult male sniffs the vulva and urine of a female to test for oestrus. The head of the male is raised, the nose pointed upwards, the lips retracted and the nose wrinkled. This muscular contraction opens the *ductus incisivus* ensuring that scent molecules reach the Jacobsen's organ for olfactory analysis.

FN: (*abbrev.*) *see* fundamental number.

foliaceous: (*adj.*) resembling the leaf of a plant.

folivore (*adj.* **folivorous**): an animal that eats leaves.

foramen (*pl.* **foramina**): an aperture (which is usually small, round or elliptical) in a bone, or between bones, for the passage of a nerve, blood vessel or muscle.

foramen magnum: the large opening at the posterior end of the skull through which the spinal cord passes.

form: a neutral term for a single individual or taxonomic unit that may be employed without reference to the formal taxonomic hierarchy of categories; one of the varieties found in a polymorphic species.

forest island: *see* relict forest.

fossa (*pl.* **fossae**): a depression or hollow usually in a bone (e.g. glenoid fossa, preorbital fossa)

fossorial: adapted for digging; burrowing. *cf.* subterranean (*q.v.*).

founder effect: the loss of genetic diversity that occurs when a new isolated population is derived from a very small number of individuals.

fovea: small pit or depression.

frontal bone: one of a pair of bones forming the anterior part of the braincase.

frugivorous: fruit-eating.

fundamental number (FN): an ambiguous term sometimes defined as (1) the total number of chromosomal arms in the full chromosomal complement of an organism (i.e. including the sex chromosomes), or (2) the total number of chromosomal arms found in the autosomal chromosomes only (i.e. excluding the sex chromosomes). When only the autosomal chromosomes are included, some authors (but not all) use aFN instead of FN to avoid ambiguity. For further details, *see* aFN.

fusiform: elongated and tapering at both ends.

fynbos: the heath shrublands characteristic of the Cape Floristic Kingdom (within the South-West Cape Biotic Zone) of South Africa. Dominant plants are sclerophyllous, evergreen, low (<3 m), bushy and fine-leaved, but there are also scattered taller bushes and, less often, very widely spaced trees. Contains an exceptionally high number of endemic species of plants. The three main components on nutrient-poor sandy soils are species of Ericaceae, Restionaceae and Proteaceae. Also includes 'renosterveld' (*q.v.*) (dominated by species of Asteraceae) on nutrient-rich silt or clay soils.

G. R.: (*abbrev.*) Game Reserve.

gallery forest: type of forest outlier (in a savanna region) found in narrow sheltered valleys and ravines on hillsides, where soils are moist enough, and conditions humid enough, to support rainforest trees (Rosevear 1953).

garrigue: a type of short, Mediterranean shrubland (White 1983).

genetic drift: in population genetics, refers to changes in the frequencies of genes in small, isolated populations that occur with time, as a result of random sampling events as opposed to natural selection.

genotype: genetical term to describe the genetic constitution of an individual inherited from its parents. *cf.* phenotype (*q.v.*).

genus (*pl.* **genera**): taxonomic division superior to species and subordinate to family.

geocarpic: having fruit that mature underground.

geophagy (= **geophagia**): the eating of saline or calcareous soil.

gestation: the development of embryo/foetus, which takes place in the uterus; the period during which this development takes place. The gestation period is defined as the interval between conception and parturition (birth). Strictly speaking, the gestation period is not the interval between copulation (mating) and parturition (birth), although many authors take it to be this interval. The gestation period (*sensu stricto*) may be lengthened by reproductive delays, such as delayed implantation (*q.v.*).

glans penis: the bulbous tip of the penis.

glenoid (= **glenoid fossa**): the cavity (fossa) in the squamosal bone of the skull for the articulation of the condyle of the mandible (lower jaw) in mammals; visible on lateral and/or ventral views of skull depending on the taxon.

GLS: (*abbrev.*) greatest length of skull, measured from anterior end of incisor teeth or nasal bone (whichever is most anterior) to the posterior end of the skull (occiput, occipital condyles or auditory bullae, whichever is most posterior).

Gondwana (= **Gondwanaland**): the southernmost of the two Mesozoic (*q.v.*) supercontinents that later fragmented (as a result of continental drift) into the landmasses of Africa, Madagascar, Antarctica, Australia, South America, the Indian subcontinent and the Arabian peninsula.

Graafian follicle: the structure in the mammalian ovary that contains the developing ovum and from which the ovum is released at the time of ovulation.

gracile: lightly built. *cf.* robust.

graminivore (*adj.* **graminivorous**): feeding on grasses.

granivore (*adj.* **granivorous**): an animal that eats grains and seeds.

graviportal: having limbs adapted to bearing great weights (as in elephants).

gregarious: living together in groups, flocks, herds.

Gregorian Rift Valley: *see* Rift Valley.

guard hair: long thin bristle-like hairs, mainly on the back and flanks that project beyond the soft hairs of the pelage; when present, conspicuous but never as numerous as soft hairs; probably tactile in function.

gular: pertaining to the upper part of the throat (the gula) as in gular gland, gular pouch, gular region.

GWS: (*abbrev.*) greatest width of skull, usually measured across the widest point of the zygomatic arches (*q.v.*).

- haematopoietic** (*n.* **haematopoensis**): pertaining to the formation of blood cells from stem cells.
- hallux**: the first digit of the hindlimb.
- hammada**: flat plain covered with pebbles of various sizes on a hard substrate in an arid environment. Much of the Sahara Desert is formed of hammada.
- haplotype**: the set of alleles borne on one of a pair of homologous chromosomes; a group of genes that is inherited together from a single parent.
- HB**: (*abbrev.*) length of head and body (measured from the tip of the nose to the most posterior point of the pelvis (anterior to the first tail vertebra)).
- hemidiaphragm**: half of the diaphragm, the muscle that separates the chest cavity from the abdomen and that serves as the main muscle of respiration.
- hermaphrodite** (*adj.* **hermaphroditic**): an individual having both male and female reproductive organs.
- heterospecific**: (*adj.*) belonging to different species. *cf.* conspecific (*q.v.*)
- heterothermic**: condition when the body temperature fluctuates in relation to the ambient temperature T_a (*q.v.*). *cf.* homeothermic (*q.v.*).
- heterozygosity**: a measure of the genetic variation in a population, expressed through the presence of different alleles (*q.v.*) at one or more loci on homologous chromosomes.
- HF**: (*abbrev.*) length of hindfoot (measured from the 'ankle bone' to the tip of the longest digit usually without including the claw). *See also* c.u.; s.u.
- hibernaculum** (*pl.* **hibernacula**): a place, domicile or roost where an animal hibernates.
- hibernation**: a state of inactivity accompanied by a reduction in metabolic rate (below basal metabolic rate [*q.v.*]), lower T_b , and slow breathing. Occurs when T_a is low and food is scarce; usually lasts for weeks or months; not common in African mammals (*cf.* torpor).
- high forest**: rainforest that has matured, stabilized and reached the climax stage of succession.
- highveld**: high plateaux characteristic of inland southern Africa, dominated by grasses.
- Holocene**: geological Epoch (within the Quaternary Period) (*q.v.*) following the Pleistocene Epoch (*q.v.*); ca.11,000 mya to today. Sometimes referred to as the 'Recent' Epoch.
- holotype** (= **type**): the single specimen designated or indicated by the original author of the original description of a new species or subspecies, to be the standard reference to the essential characters of the new taxon. *see also* cotype (*q.v.*), lectotype (*q.v.*), neoparatype (*q.v.*), neotype (*q.v.*), paratype (*q.v.*), syntype (*q.v.*), topotype (*q.v.*) and type locality (*q.v.*).
- home-range**: the area (expressed in square metres, or square kilometres) routinely used by an animal for its day-to-day activities and requirements, and that contains the resources required for survival and reproduction. Within the home-range there may be a 'core area' or 'centre of activity' that is utilized more frequently than other parts (e.g. 80% or 90% of known time-based observations). *cf.* territory (*q.v.*).
- homeothermic**: describes an organism having a body temperature that is maintained at a constant level (within limits), independently of the ambient temperature T_a (*q.v.*). For the limits, *see* upper and lower critical temperatures [*q.v.*]. *cf.* heterothermic (*q.v.*).
- homoplasy**: similarity between different organisms or taxa resulting from evolution along similar lines (e.g. convergent evolution) rather than descent from a common ancestor.
- homozygous** (*n.* homozygosity): describes a diploid organism that has inherited the same allele of any particular gene from each of its parents. *cf.* heterozygous.
- hyoid**: a small bone or bones in the throat located at the base of the tongue and supporting the muscles of the tongue.
- hyperthermia**: elevation of body temperature above normal limits due to increase in T_a (*q.v.*) or increase in metabolic rate. *cf.* hypothermia (*q.v.*).
- hypoconulid**: the most posterior cusp on the lingual (inner) side of a lower molar tooth.
- hypogeal**: living or growing underground.
- hypothermia**: drop in body temperature below normal limits; occurs in some small mammals when T_a (*q.v.*) falls, and is a means of conserving energy in cold weather. *cf.* hyperthermia (*q.v.*).
- hypodont**: describes a premolar or molar tooth with high crowns; has short roots. *cf.* bunodont, lophodont.
- I or i**: (*abbrev.*) incisor (*q.v.*) tooth or teeth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* incisor.
- I.** (*pl.* **Is.**): (*abbrev.*) Island.
- I¹-M³**: (*abbrev.*) the length of the upper tooththrow from the anterior end of the first upper incisor to the posterior end of the last molar. In taxa where the last molar is M¹ or M² (instead of M³), the measurement is I¹-M¹ or I¹-M².
- implantation**: the embedding of a blastula (*q.v.*) in the lining of the uterus.
- incertae sedis**: (*Lat.*) refers to a taxon of uncertain status and that is perhaps taxonomically invalid.
- incisive foramen** (*pl.* **foramina**): paired foramina located at the anterior end of the bony palate, just posterior to the incisor teeth.
- incisor**: tooth rooted in the premaxillary bone (most anterior bone of upper jaw) and in an equivalent position in the mandibular bone (lower jaw); always anterior to the canine teeth, if present. The number and form of the incisor teeth varies in different species. *See also* dental formula (*q.v.*).
- infraorbital foramen** (*pl.* **foramina**): foramen that connects the orbit (eye-socket) with the rostrum (premaxilla and maxilla bones); this foramen contains the masseter medialis muscle in some taxa. Also referred to as anteorbital foramen and antorbital foramen.
- infrasonic**: describes sounds with frequencies below the range that can be heard by humans.
- infundibulum**: a funnel-shaped cavity or depression.
- inguinal**: situated in the groin, that is the area between the lower lateral part of the abdomen and the thigh.
- inner**: nearest to mid-line of body, e.g. inner incisor, inner margin of ear.
- insectivore** (*adj.* **insectivorous**): an animal that eats insects.
- inselberg**: isolated rocky hill; term used mainly in western Africa. *See also* jebel (*q.v.*); kopje (*q.v.*), krantz (*q.v.*).
- inter-aural**: between the ears.
- inter-digital**: between the digits (e.g. interdigital gland).

- inter-orbit (= inter-orbital constriction):** narrowest part of the skull between the orbits when viewed dorsally at the level of the frontal bones.
- inter-parietal:** bone (not paired) on dorsal surface of the skull, lying between and partly posterior to the parietal bones.
- inter-pterygoid region:** the region between the two plate-like pterygoid bones (*q.v.*) that form part of the roof of the mouth.
- inter-specific:** between different species.
- intra-specific:** within one species; between members of the same species.
- intromission:** insertion of the penis into the vagina during copulation.
- invagination:** the formation of a cavity by the in-sinking of the outside wall or surface of a tissue or structure, thereby drawing an exterior layer into the interior of the structure to form the lining of the cavity; a cavity formed by the process of invagination.
- Isoptera:** taxonomic order containing the termites (within the phylum Insecta).
- isozyme:** any one of several different forms of an enzyme encoded by the same or different genes and that each differ in properties such as optimum pH or isoelectric point.
- iteroparous:** repeated reproduction throughout a season or a lifetime (*cf.* semelparous – reproduces once and then dies).
- ivory:** *see* dentine.
- jebel (= gebel):** isolated rocky hill in savanna and arid habitats; term used mainly in northern Africa. *See also* inselberg (*q.v.*); kopje (*q.v.*).
- jugal:** bone of the skull that forms the middle part of the zygomatic arch (*q.v.*); anteriorly joins the maxillary process (*q.v.*) of the maxilla bone and posteriorly joins the squamosal process of the squamosal bone.
- K-selection:** selection for characteristics suitable in stable environments (slow development of young, small litter size, relatively long time to maturity, relatively long life span) *cf.* r-selection (*q.v.*).
- Kaokoveld:** area of sandstone and lava hills of the Namib Desert (Biotic Zone 11b) in NW Namibia, inland from the Skeleton Coast.
- Karoo:** southern African term for grassy dwarf shrubland on the semi-arid central plateau of the western half of South Africa at altitudes of 500–2000 m.
- karyogram:** a photographic representation of a karyotype (*q.v.*) as it appears at mitosis. Individual chromosomes are arranged in pairs from largest to smallest.
- karyological:** pertaining to the nucleus and chromosomes.
- karyotype:** the chromosomes in the cell of an animal. *See also* karyogram.
- kloof:** a deep, narrow valley or gorge.
- kopje:** rocky hill with boulders, rock crevices and sparse vegetation; term used mainly in southern Africa. *See also* inselberg (*q.v.*); jebel (*q.v.*); kranz (*q.v.*).
- krantz (pl. krantzes):** a wall of rock encircling a mountain or summit; hence any precipitous or overhanging wall of rocks.
- L.:** (*abbrev.*) Lake.
- labial:** pertaining to the lips; situated near the lips; on the outer side of the teeth within the mouth. *cf.* lingual (*q.v.*).
- labially:** in the direction of the lips. *cf.* lingually (*q.v.*).
- lachrymal bone:** small bone in skull situated at the upper anterior margin of the orbit, near the lachrymal (tear) gland.
- lambdoid crest:** *see* supraoccipital crest.
- lamina (pl. laminae):** in the context of premolar and molar teeth, a transverse row of cusps (e.g. t1, t2 and t3, or t4, t5 and t6, etc.) that, when worn, form a transverse ridge of bone and dentine across the tooth.
- larynx (= voice box):** the structure in the throat of mammals that produces sound.
- lauschlag:** a courtship behaviour in antelopes in which the male touches the female's underside with a stiff foreleg, placing it either under her flank from the side or between her hind legs from behind. Also termed the mating kick or foreleg kick.
- Laurasia:** the northernmost of the two Mesozoic (*q.v.*) supercontinents that later fragmented (as a result of continental drift) into the landmasses of Europe, Asia (excluding the Indian subcontinent) and North America.
- lectotype:** a specimen chosen from syntypes (*q.v.*) to stand as 'the type' of a species or subspecies when no holotype (*q.v.*) was designated by the author who described the new species or subspecies.
- lek:** a traditional site where males gather for the sole purpose of attracting and courting females, and to which females come for the sole purpose of mating with the male of their choice.
- limiting factor:** the principle that the growth or functioning of an organism is limited when any essential factor (or resource) is lacking or in short supply, regardless of the quantity available of any other factor (or resource). The principle may also be applied to the proliferation and/or distribution of a population or species.
- lingual:** pertaining to the tongue; situated near the tongue; on the inner (tongue) side of the mouth. *cf.* labial (*q.v.*).
- lingually:** in the direction of the tongue. *cf.* labially (*q.v.*).
- litter-size:** number of young born to a female. Expressed as mean number (with range from minimum to maximum, and sample size). *cf.* embryo number (*q.v.*).
- localized movements:** movements of an animal within part or all of its home-range within a single day or within a limited period of time. *cf.* migration (*q.v.*); nomadic movements (*q.v.*).
- longitudinal:** lengthwise; running in a head to tail direction. *cf.* transverse (*q.v.*).
- lophodont:** molar teeth having the crowns formed in transverse crests or ridges (*cf.* bunodont).
- lordosis:** dorsi-flexion of the spine, often performed by females prior to copulation.
- lower critical temperature:** the lowest ambient temperatures at which the animal must increase its metabolic rate to maintain a constant body temperature. If ambient temperature decreases further, and the animal is unable to increase its metabolic rate sufficiently to maintain a constant body temperature, it will enter hypothermia and may eventually die. *cf.* upper critical temperature.
- lowveld:** savanna at lower altitudes below the Great Escarpment of South Africa, with vegetation consisting of a grassy lower layer and a woody upper layer of shrubs and/or trees, at either high density (woodland) or intermediate density (bushveld, *q.v.*).
- lumbar:** describes vertebrae between the thoracic vertebrae and the sacrum; vertebrae of the lower back in humans.

lyrate: having curvature suggestive of a lyre.

M: (*abbrev.*) molar tooth or teeth. *See also* molar (*q.v.*).

Maghreb: *see* North-West Africa (*q.v.*).

malleus: the most external bone of the three ossicles of the middle ear, the handle of which is joined to the ear drum.

mandible: lower jaw.

mandibular ramus: one of the two branches (sides) of the mandible (*q.v.*); the two rami are joined at the mandibular symphysis (*q.v.*).

mandibular symphysis: the junction, marked by a small vertical ridge, where the left and right sides of the mandible are fused.

masseter muscle: one of the muscles that raises the lower jaw, e.g. during chewing. Particularly well developed and powerful in herbivores.

mastoid: one of a pair of bones, often with a prominent process, situated near the posterior end of the skull behind the auditory meatus (*q.v.*).

matriarchal; describes social groups dominated and/or led by a female (often one of the oldest females in the group).

maxilla (*pl. maxillae*): one of the pair of bones in the skull that forms that part of each upper jaw in which the canine (*q.v.*) (if present) and cheekteeth (premolars and molars) (*q.v.*) are rooted.

maxillary process: projection of bone from the maxilla that forms the anterior portion of the zygomatic arch (*q.v.*); usually orientated vertically to the anterior–posterior line of the skull.

maxillary: pertaining to the maxilla (*q.v.*).

meatus: a passage or channel; the opening of a passage.

medial: situated in the middle.

melanistic: having an abnormally large amount of black or dark pigment in pelage and skin.

mesa: Ethiopian word for the microhabitat (usually on slopes) within afroalpine moorlands and grasslands, where it is higher and drier than surrounding areas, so dominated by (usually) *Alchemilla*.

Mesozoic (= Mesozoic Era): geological era; ca. 250–ca. 65 mya, comprising the Triassic, Jurassic and Cretaceous Periods; the Age of Reptiles.

metabolic rate: *see* basal metabolic rate (*q.v.*).

metabolic water: water produced by oxidative processes within the body; an important source of water for arid-adapted mammals when free (drinking) water and water within the food is in short supply or unavailable.

metacarpals: the long bones of the hand, situated between the carpal bones of the wrist and the proximal phalanges of the fingers.

metacentric: describes a chromosome with the centromere (*q.v.*) at or very near the middle of its length, so there are two arms of equal or almost equal length (ratio not greater than 1 : 1.1). *cf.* submetacentric (*q.v.*).

metacone: the posterior labial (external) cusp of an upper molar tooth.

metacromion: a process projecting backward and downward from the acromion (the lateral triangular projection of the spine of the scapula that forms the point of the shoulder and articulates with the clavicle of the scapula) of some mammals.

metapopulation: in population dynamics and ecology, a group of spatially separated populations of the same species that interact at some level.

metatarsal gland: scent glands on the outside lower hind leg. In the Bovidae, only the Impala *Aepyceros melampus* possesses metatarsal glands.

metatarsals: the long bones of the foot, situated between the tarsal bones of the ankle and the most proximal phalanges of the toes.

microcomplement fixation: in molecular evolutionary studies, species can be compared by the extent to which antibodies to the proteins of one species cross-react to the proteins of another species. The extent of cross-reaction is indicative of the similarity of the proteins and, by inference, the evolutionary affinity of the two species. Albumin is a protein commonly used for these studies.

microsatellite locus (*pl. microsatellite loci*): a region within a DNA sequence where short sequences of one, two, three or four of the nucleotides (A [adenine], T [thiamine], G [guanine] and C [cytosine]) are repeated consecutively; e.g. ACACAC, CAACAA. The number of times a sequence is repeated varies between individuals, within populations of a species, or between species, which makes microsatellite loci useful tools in systematics (*q.v.*).

migration: movements of species that travel, predictably and more-or-less directly, from one habitat to another (and back again), along predetermined routes, in response to seasonal changes in climate, food supply or any other resource. *cf.* localized movements (*q.v.*); nomadic movements (*q.v.*).

milk teeth: teeth occurring in newborn mammals, or appearing soon after birth, and preceding the permanent teeth of the adult animal. Also called deciduous teeth.

Miocene: geological Epoch (within the Tertiary Period); ca. 23–5 mya.

miombo: a vernacular name applied to trees in the genus *Brachystegia*; a type of savanna woodland in the Zambezi region where *Brachystegia* spp. are the commonest trees or one of the commonest trees.

Mistbelt: foothills along the eastern Great Escarpment that experience regular fogs, with vegetation comprising mainly grasslands and patches of afroalpine forest in protected valleys and ravines.

mitochondrial DNA: the small amount of DNA contained within the mitochondria of a cell.

molar: grinding or cutting tooth rooted in the maxilla bone and the mandible; there are usually one, two or three molar teeth in each ramus of the jaw. Together with the premolars, if present, they form the 'cheekteeth'. The number and form of the molar teeth varies in different species. Not preceded by deciduous (milk) teeth.

molariform: similar in form to a molar tooth; used to describe the form of the premolar teeth in some taxa.

monoestrous: Generally, having one oestrus cycle (*q.v.*) during a single reproductive season. In some taxa, having one litter per year. *cf.* polyoestrous (*q.v.*).

monogamy (*adj. monogamous*): a mating system in which one male mates with one female. Neither sex has the opportunity of monopolizing additional members of the opposite sex. Fitness often maximized through shared parental care (Emlen & Oring 1977). *cf.* polygyny (*q.v.*).

monophyletic: describes a taxonomic group descended from a common ancestor that was itself a member of that taxonomic

- group, and including *all* the descendants of that ancestor (Groves 2001). *cf.* paraphyletic (*q.v.*); polyphyletic (*q.v.*).
- monophyly**: derivation of taxa from a common ancestor. *cf.* diphyly (*q.v.*), polyphyly (*q.v.*).
- monospecific**: describes a genus containing only one known species. *See also* monotypic (*q.v.*).
- monotocous**: normally having only one young per litter (twinning, if it occurs, is very rare and abnormal). *cf.* polytocous (*q.v.*).
- monotypy** (*adj.* **monotypic**): describes a taxon containing only one immediately subordinate taxonomic unit, e.g. a monotypic family contains only one genus; a monotypic genus contains only one species. *cf.* polytypy (*q.v.*).
- mopane**: a vernacular name applied to the tree *Colophospermum mopane*; a type of savanna woodland in the Zambezi region in which *C. mopane* is the commonest species of tree.
- Mt.** (*abbrev.*) Mount.
- mtDNA**: (*abbrev.*) mitochondrial DNA (*q.v.*).
- Mts.** (*abbrev.*) Mountains.
- multiparous**: describes either the birth of more than one offspring at once, or a female that has given birth two or more times.
- muzzle**: the snout; the nose and jaws of a mammal.
- MW**: (*abbrev.*) *see* mastoid width.
- mya**: (*abbrev.*) millions of years ago.
- myrmecophagy** (*adj.* **myrmecophagous**): the eating of ants and/or termites.
- mystacine vibrissae**: vibrissae (*q.v.*) resembling a moustache.
- n. d.**: (*abbrev.*) no data.
- N. P.**: (*abbrev.*) National Park.
- N. R.**: (*abbrev.*) Nature Reserve (not National Reserve).
- nares** (*pl.* **nares**): a nostril.
- Neogene Period**: geological period and system; 23.03 ± 0.05 to 2.5 mya, comprising the second part of the Cenozoic Era.
- neonate**: a newly born animal.
- neoparatype**: any specimen described at the same time as the neotype (*q.v.*).
- neotype**: a specimen selected as the type in cases where the primary types are definitely known to be lost or destroyed.
- nipple**: external opening of mammary gland. Nipple number and position vary according to the taxon, but are consistent within a species. Nipples arranged in pairs, one of the pair on each side of body.
- nocturnal**: at, active in, the night; when light intensity is at its lowest; between sunset and sunrise. *cf.* crepuscular (*q.v.*); diurnal (*q.v.*).
- nomadic movements**: irregular and unpredictable movements, from one locality to another, made by species living in unpredictable habitats. *cf.* localized movements (*q.v.*); migration (*q.v.*).
- nomen dubium**: when the available evidence is not sufficient to permit the identification of a species, its name is considered to be a *nomen dubium* and therefore not available for taxonomic purposes.
- nomen nudum**: a name that is not valid because, when it was originally published, the organism to which it referred was not adequately described, defined or sketched. The name is therefore invalid because it is impossible to associate it indisputably with any specific organism.
- nominate subspecies**: the subspecies that bears the name of the species to which it belongs (e.g. *Otocyon megalotis megalotis*), only brought into existence by the creation of one or more other subspecies in the same species (e.g. *Otocyon megalotis virgatus*).
- North Africa**: those parts of Mauritania, Morocco, Algeria, Tunisia, Libya and Egypt that are north of the Sahara Desert.
- North-Central Africa**: Southern Chad and southern Sudan, west of the Nile R. and south of the Sahara. Mainly savanna habitats.
- North-West Africa (= Mahgreb)**: those parts of Mauritania, Morocco, Algeria, Tunisia and NW Libya that are north of the Sahara Desert.
- nuchal**: pertaining to the nape of the neck.
- nulliparous**: not having given birth.
- obligate**: obligatory; limited to one mode of life or action irrespective of conditions or circumstances. *cf.* facultative (*q.v.*).
- occipital condyles**: the pair of smooth, rounded processes of the occipital bone at the posterior end of the skull on either side of the occipital foramen that acts as a hinge between the head and the neck.
- occiput**: the posterior part of the skull, above the foramen magnum (*q.v.*).
- occlusal**: pertaining to the biting surface of a tooth.
- oestrous cycle**: the reproductive cycle in most non-pregnant female mammals, comprising recurring physiological changes induced by reproductive hormones.
- oestrus** (*adj.* **oestrous**): The period when a female is sexually receptive.
- Oligocene**: geological Epoch (within the Tertiary period), ca. 38–23 mya.
- omnivore** (*adj.* **omnivorous**): an animal that eats a wide range of foods.
- orbit**: bony cavity (eye-socket) in which the eye is situated.
- oscillogram**: a visual representation (graph) of sound waves in which amplitude (sound wave pressure) is plotted on the vertical axis, and time on the horizontal axis (*cf.* sonogram *q.v.*).
- osmetrichia**: hairs structurally specialized for the dispersal of scent.
- osteophagia**: the chewing on bones engaged in by herbivorous animals suffering from a deficiency of phosphorus and calcium in their diet.
- outer**: furthest from the mid-line of the body.
- ovulation**: the release of female gametes (ova, eggs) from the ovary.
- ovum**: the female gamete or egg cell.
- owl pellets**: waste material, normally in an egg-like shape, regurgitated by owls, which contains undigested fragments of bone, hair, feathers and scales etc. from the prey; for mammalogists, useful in determining indirectly the species of small mammals in a habitat.
- P or p**: (*abbrev.*) premolar tooth or teeth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* premolar.
- pachyosteosclerosis**: a thickening of the bones of the ribs and vertebrae, resulting in unusually solid bone structure with little to no marrow.
- Palaeartic**: a zoogeographic region comprising Europe, North Africa and Asia (except for southern portion of the Arabian Peninsula and tropical and sub-tropical parts of the Oriental Region).
- Palaeocene**: geological Epoch (within the Tertiary Period); 65–55 mya.

- palatal foramen** (*pl.* foramina): a foramen (*q.v.*) in the palatine bone.
- palate**: the roof of the mouth. The anterior part (hard palate) comprises the bony palate (formed by the premaxillae, maxillae and palatine bones), and a covering mucous membrane. The posterior part (soft palate) is composed only of muscular tissue covered by a mucous membrane.
- Paleogene**: geological period and system; 65.5 ± 0.3 to 23.03 ± 0.05 mya, comprising the first part of the Cenozoic Era.
- papilla** (*pl.* papillae, *adj.* papillate): a small projection or protuberance.
- paraoccipital process**: narrow strut-like bone that projects ventrally from the paraoccipital bone on the posterior part of the skull.
- parapatry** (*adj.* parapatric): the situation where two or more species have geographic ranges that are contiguous (*q.v.*) but do not overlap. This abutting may be along a line of habitat discontinuity, ecotone, or altitudinal/climatic contour, but may also arise from competitive exclusion of one (or both) by the other.
- paraphyletic**: describes a taxon containing units that have evolved from a single ancestral taxon but that do not contain all of the descendents of the most recent common ancestor.
- paratype**: a specimen collected at the same time and place as the holotype (*q.v.*) and designated by the original authority as such. There may be one or more paratypes.
- parietal**: one of the pair of bones forming the vault of the braincase, situated between the frontal and the occipital bones.
- parous**: having given birth.
- partim**: in taxonomy, used in context of taxon names and synonyms to indicate that not all material that has been referred to the name is currently considered to belong to that name. e.g. *auritus* (partim) is listed as a synonym of *Plecotus christii* because only some of the specimens, which were earlier identified as *Plecotus auritus*, are now considered to represent *P. christii*.
- parturition**: the act of giving birth.
- pectoral**: pertaining to or situated on the chest.
- pedal glands**: glands that are situated in the feet opening between the hooves.
- pelage**: the hairy, woolly or furry covering of the body in mammals. The pelage variously consists of hairs, guard hairs and underfur according to the species.
- petrophily** (*adj.* petrophilic): occupying habitats dominated by large boulders.
- phalanx** (*pl.* phalanges): one of the bones in a finger.
- pharynx** (*adj.* pharyngeal): the passage leading from the oral and nasal cavities in the head to the oesophagus and larynx (*q.v.*).
- phenotype**: the visible characters of an individual resulting from the interaction between the genotype (*q.v.*) and the environment.
- philopatry**: the tendency to remain in or consistently return to the place where one was born.
- philtrum**: a medial vertical cleft or groove in the rhinarium (*q.v.*) extending from between the nostrils to the upperlip.
- phylogenetics**: pertaining to the line of descent of a taxon; a method of classification that attempts to show the evolutionary relatedness of organisms.
- phylogeny** (*adj.* phylogenetic): the evolutionary history and line of descent of a species or higher taxonomic unit.
- piloerection**: the erection of hairs that occurs as a means of conserving heat (*see* temperature regulation) and, in some mammals, as a threat display.
- pinna** (*pl.* pinnae): the external (outer) ear.
- placental scars**: scars on the inner surface of the uterus of a mammal; the site where a placenta was attached during pregnancy. The number of placental scars can give an indication of the number of litters that a female has had (when the average number of young/litter is known).
- placentation**: the formation, type and structure of the placenta; the arrangement of placentae.
- plantar**: of the sole of the foot.
- plantigrade**: describes locomotion during which the entire sole of each foot touches the ground.
- Pleistocene**: geological Epoch (within the Quaternary Period); ca. 1.7 mya to 10,000 year ago.
- plesiomorphy** (*adj.* plesiomorphic): in cladistics (*q.v.*), describes a pre-existing character state across a wide taxonomic grouping. Sharing of that state (symplesiomorphy [*q.v.*]) amongst a subset of taxa within the wider grouping is not indicative of monophyly (*q.v.*). *cf.* apomorphy (*q.v.*).
- pleural cavity**: the body cavity occupied by the lungs.
- Pliocene**: geological Epoch (within the Tertiary period), ca. 2–5 mya.
- poikilothermic**: the condition when the body temperature varies with the surrounding ambient temperature.
- pollex**: digit 1 ('thumb') of forefoot ('hand').
- polygyny** (*adj.* polygynous): a mating system in which one male mates with several females. *See* resource-defence polygyny; female-defence polygyny. *cf.* monogamy (*q.v.*).
- polymorphism** (*adj.* polymorphic): the existence, within a species or population, of individuals having different forms (colour, size, shape etc.).
- polyoestrous**: Generally, having two or more oestrous cycles (*q.v.*) during a single reproductive season. In some taxa, having more than one litter/year. *cf.* monoestrous (*q.v.*).
- polyovulation**: production of many ova (and hence many corpora lutea) during a single oestrus; sometimes called 'superovulation'; recorded in some species of sengis.
- polyphyletic**: describes a taxon derived from two or more ancestral sources; not of a single, immediate line of descent (Mayr *et al.* 1953). *cf.* monophyletic (*q.v.*).
- polyphyly**: derivation of a taxon from two or more ancestral sources. *cf.* monophyly (*q.v.*).
- polytocous**: normally or often having more than one young per litter. *cf.* monotocous (*q.v.*).
- polytypy** (*adj.* polytypic): a taxon that has several taxa in the next lower taxonomic category, e.g. a polytypic family contains two or more genera, a polytypic genus has two or more species. *cf.* monotypy (*q.v.*).
- postauricular**: behind the external ear (pinna).
- postorbital process**: the bony projection arising from upper rim of orbit and projecting outwards and downwards around the posterior of the orbit.
- postorbital**: behind (posterior to) the orbit.
- postpartum oestrus**: an oestrus cycle immediately after (or very soon after) parturition and while lactating.

- precocious** (= **precocial**): describes young born in a well developed state enabling them to move around and forage soon after birth. *cf.* altricial (*q.v.*).
- premaxilla** (*pl.* **premaxillae**): one of a pair of bones at the anterior end of the skull that bears the incisor teeth.
- premolar**: tooth on the maxilla bone situated immediately anterior to the molar teeth; usually preceded in time by deciduous (milk) tooth; multi-cusped. Structure and function of premolar teeth vary according to species.
- preorbital fossa**: a bilateral depression in the skull, located anterior to the eye.
- preorbital**: anterior to the eye.
- prepuce** (*adj.* **preputial**): the skin surrounding and protecting the head of the penis; foreskin.
- preputial gland**: a gland situated adjacent to the penis or vaginal opening.
- primiparous**: a female that has given birth only once. *cf.* multiparous (*q.v.*).
- promiscuity**: a mating system in which each male mates with several females and each female mates with several males.
- pronking**: *see* stotting.
- protocone**: The main inner (lingual) cusp of an upper molar tooth.
- protuberant**: projecting forward (bulging) beyond the surrounding surface.
- proximal**: nearest to the body or to the mid-line of the body; nearest to the point of attachment. *cf.* distal (*q.v.*).
- proximate cause**: a cause that produces an effect directly without any intervening agency.
- pterygoid process**: one of a pair of narrow, ventrally projecting processes of the pterygoid bones situated immediately posterior to the bony palate and forming the walls of the mesopterygoid fossa (*q.v.*).
- pterygoid**: one of a pair of cranial bones forming part of the roof of the mouth.
- pubic bone**: anterior inferior part of the pelvis, articulating with its opposite number in the anterior midline at the pubic symphysis.
- Quaternary Period**: period within the Cenozoic Era; 2 mya to today, comprising two epochs: the Pleistocene and Holocene (Recent) (*q.v.*).
- r-selection**: selection for characteristics suitable in unstable fluctuating environments (rapid development of young, large litter size, relatively short time to maturity, relatively short life span) *cf.* K-selection (*q.v.*).
- R.**: (*abbrev.*) River.
- radius**: one of the two bones of the lower forelimb between the humerus (upper arm) and the wrist.
- ramus**: one half (left or right) of the lower jaw or mandible.
- range length**: distance between the most distant captures (by live-trapping) of an individual; a rough method of assessing home-range (*q.v.*).
- Recent**: *see* Holocene (*q.v.*).
- relict forest**: a forest that persists where local conditions are favourable after the disappearance of forest from the surrounding area as a result of climate change or human activity. Relict forests include those at the base of inselbergs that are watered by rainwater running off the inselberg, and forests growing in graveyards and sacred sites that are protected. Sometimes known as forest islands.
- relict population**: one that persists where local conditions are favourable after the extinction of the species from at least part of its former range.
- Renosterveld**: a dominant vegetation type in the Cape Floristic Region (*q.v.*), and characterized by the dominance of members of the Daisy Family (Asteraceae), specifically one species - Renosterbos *Elytropappus rhinocerotis*, from which the vegetation type gets its name.
- reproductive capacity**: number of young produced by a female during the breeding season.
- reproductive chronology**: the timing and duration of events, such as spermatogenesis, copulation, ovulation, gestation, parturition, lactation and reproductive inactivity, throughout the year.
- reproductive strategy**: the strategy adopted to maximise reproductive success, determined primarily by litter-size and reproductive chronology (*q.v.*).
- resource-defence polygyny**: a mating system in which a male controls access to several females indirectly, by monopolizing critical resources (Emlen & Oring 1977).
- retarded embryonic development**: a means of lengthening the interval between copulation and parturition so that both events can occur in the most optimal seasons. The implanted embryo enters a period of retarded (slowed) growth that may last 4–8 months, after which development proceeds normally.
- reticulation** (*adj.* **reticulated**): having a net-like pattern.
- rhinarium**: area of naked moist skin surrounding the nostrils.
- ridge** (= **commissure**): in teeth, a ridge connecting two cusps.
- Rift Valley**: deep valley extending from the Red Sea through Ethiopia and East Africa to Malawi; formed ca. 12 mya by subsidence of the valley floor and uplifting of the edges to form mountains and highlands. Four parts: (1) Ethiopian Rift Valley dividing the Ethiopian plateau into two parts; (2) Albertine Rift Valley (Western Rift Valley) in Uganda, E DR Congo and W Tanzania; (3) Gregorian Rift Valley (Eastern Rift Valley) in N Kenya, C Kenya and N Tanzania; (4) Malawian Rift Valley – the extension of the Albertine Rift Valley in Malawi. The Rift Valleys are noted for their many deep and beautiful lakes.
- riparian**: growing on or living on the banks of streams or rivers.
- riverine forest**: forest growing along the banks of a river or stream where conditions are moister than in the surrounding area. Sometimes referred to as ‘fringing forest’.
- Robertsonian fusion**: a chromosomal event involving the apparent fusion of non-homologous single armed (telocentric *q.v.*) chromosomes to form a bi-armed (metacentric *q.v.* or submetacentric *q.v.*) chromosome. Modern studies have revealed that all chromosomes have two arms, even if the smaller one is not detectable by light microscopy. Consequently, the term Robertsonian translocation is becoming more commonly used than Robertsonian fusion.
- rostral**: pertaining to the rostrum.
- rostrum**: that portion of the skull anterior to the front line of the orbits and supporting the upper part of the muzzle, comprised of the nasals, premaxillae and maxillae bones.
- rupicolous**: rock-living.
- s.u.**: (*abbrev.*) (*Lat. sans unguis* = without claw) sometimes added as a suffix to the hindfoot measurement to emphasize that HF has been

- measured without the claw. However, since this is the standard method of measurement, most authors write 'HF', not 'HF s.u.'. *cf.* c.u. (*q.v.*).
- sacrum** (*adj.* **sacral**): the fused vertebrae to which the pelvic girdle is attached.
- sagittal crest**: longitudinal crest of raised bone on the mid-dorsal line of the cranium.
- scansorial**: climbs or scrambles over logs and in low vegetation close to the ground. *cf.* terrestrial (*q.v.*); arboreal (*q.v.*).
- scapholunar bone**: a bone formed by the coalescence of the scaphoid and lunar in the carpus of Carnivora.
- sclerophyllous**: describes vegetation having hard leaves that are resistant to drought.
- scrotal**: pertaining to, or within, the scrotum (*q.v.*).
- scrotum**: an external sac containing the testes and epididymides in male mammals.
- sebkha**: A geological feature, in North Africa, that is a smooth, flat, plain usually high in salt (also sabkha).
- sectorial**: adapted for cutting.
- selenodont**: molar teeth having longitudinal crescent-shaped ridges.
- Senegambia**: Senegal and Gambia.
- sensu lato**: (*Lat.*) in a broad sense.
- sensu stricto**: (*Lat.*) in a strict sense.
- sensu**: (*Lat.*) in the sense of.
- septum**: a dividing wall separating two cavities.
- sex ratio**: the number of males to the number of females, usually expressed as a proportion to one male, e.g. 1 : 1 (equal numbers of males and females), 1 : 0.5 (= twice as many males as females), 1 : 2 (= twice as many females as males).
- sexual dimorphism**: observable (phenotypic) difference(s) (e.g. in colour, size or form) between the males and females of a species or higher taxon.
- Sh. Ht.**: (*abbrev.*) shoulder height (in ungulates, usually taken to be between the pegs, but sometimes measured over the curve).
- sibling species**: pairs or groups of true species that are reproductively isolated, but genetically closely related and so similar in appearance that they are difficult to separate solely on the basis of morphological characters.
- side-stripe**: longitudinal stripe(s) of contrasting colour on each flank, usually from shoulder to rump or upper part of hindlimbs. May be bordered by additional side-stripe above and below.
- singleton**: a neonate that is born singly as opposed to being one of a larger litter.
- sister species**: species that are thought to have arisen from a single dichotomous splitting event.
- sonogram**: a visual representation (graph) of sound in which frequency is plotted on the vertical axis, and time on the horizontal axis; can be analysed manually or with computer programs (*cf.* oscillogram *q.v.*).
- sounder**: a group of pigs.
- South-Central Africa**: Angola, SE DR Congo, Zambia and Malawi (but only west of L. Malawi and the Shire R. Valley).
- southern Africa**: south of the Cunene and Zambezi Rivers, i.e. Namibia, Botswana, Zimbabwe, southern Mozambique and South Africa (after Smithers 1983).
- spatulate**: like a spatula, i.e. narrow at the base but wider, flat and parallel-sided distally.
- species**: population(s) of closely related and similar organisms, which are capable of interbreeding freely with one another and cannot or typically do not interbreed with members of other species.
- sperm storage**: storage of sperm in the cauda epididymides (*q.v.*) of males for some time before copulation, or in the reproductive tract of females for an extended period before ovulation takes place. A type of reproductive delay that, in females, lengthens the length of gestation (*q.v.*).
- sperm**: any male gamete; the male cell that fuses with a female gamete (ovum, egg cell) to produce a fertilized egg or zygote from which an embryo will develop.
- spermatogenesis**: the formation of sperm in the testes.
- stotting**: bouncing up and down with legs held stiffly. Also referred to as pronking.
- sub, sub-**: prefix meaning under, signifying beneath or ventral to (as in anatomical features) or south of (as in sub-Saharan); less than (as in subsonic); not quite, nearly, almost, somewhat (as in subequal, subtriangular). In taxonomy, indicates a group just below the status of the taxa immediately following it (e.g. a genus may contain two or more subgenera).
- subauricular**: below the ear.
- subcaudal**: below the tail.
- subdermal**: just below the skin.
- submetacentric**: describes a chromosome with the centromere (*q.v.*) somewhat nearer one end than the other, so there are two arms of somewhat unequal length (ratio 1 : 1.2–1.9). *cf.* metacentric (*q.v.*); subtelocentric (*q.v.*).
- subspecies**: a geographically localized and isolated subdivision of a species, which differs genetically, morphologically and taxonomically from other subdivisions of the species.
- subtelocentric**: describes a chromosome with the centromere (*q.v.*) much nearer one end than the other, so there are two arms of very unequal length (ratio 1 : >2).
- subterminal**: just below the end or tip.
- subterranean**: living permanently below the ground; *cf.* fossorial (*q.v.*).
- suckling**: the act of a mother giving milk directly from her breast (mammary glands) to her young. Mothers suckle; their young suck.
- sulcus** (*pl.* **sulci**): a groove, fissure or furrow.
- superovulation**: *see* **polyovulation** (*q.v.*).
- supinate**: to turn or rotate the hand or forearm, or the hindlimb and foot.
- supracaudal**: above the tail.
- supraoccipital crest**: ridge of bone, orientated transversely across the back of the skull, at the junction of the parietal and/or supraoccipital bones and the occipital bone. Sometimes referred to as the lambdoid crest.
- supraorbital ridge**: ridge of bone along upper rim of orbit (eye-socket).
- supraorbital**: above (dorsal to) the orbit.
- supraordinal**: describes a taxon above the level of the order.
- sympatry** (*adj.* **sympatric**): the situation where populations of two or more different species have overlapping geographic ranges; refers also to populations of two or more species whose geographic ranges are partly or wholly overlapping. They may or may not interact. *cf.* allopatry (*q.v.*); syntopy (*q.v.*).

- symplesiomorphy**: a primitive or ancestral character shared by two or more groups, which is inherited from ancestors older than the last common ancestor.
- synanthropic**: associated with humans and/or their houses and other buildings.
- synapomorphy** (*adj.* **synapomorphic**): situation in which a homologous character is present in two or more taxa and is thought to have originated in their most recent common ancestor. *See also* apomorphy.
- syndactyly**: of digits; whole of part fusion of two or more digits (e.g. Digits 2 and 3 of the hindfoot in otter-shrews).
- synonym**: one or more of different names for the same taxonomic unit. A synonym may be a 'senior synonym' (the oldest name), or a 'junior synonym' (a more recent name) that is no longer considered as valid. May be used to refer to all names that have been associated, at some time in the past, with the taxonomic unit as currently understood.
- syntopy** (*adj.* **syntopic**): describes the situation where two or more species use the same or similar habitats and activity times. They may or may not interact. *cf.* allopatry (*q.v.*); sympatry (*q.v.*).
- syntype**: any specimen, or one of a series of specimens, used to designate a species when a holotype (*q.v.*) and paratype(s) (*q.v.*) have either not been selected, or have been lost or destroyed.
- systematics**: the science of arranging organisms in a way that reflects their evolutionary relationships; such relationships may be expressed as a phylogeny (*q.v.*). Often defined (somewhat incorrectly) as a synonym of taxonomy (*q.v.*).
- T**: (*abbrev.*) length of tail, measured from anterior of the first caudal vertebra to the posterior end of the last caudal vertebra (excluding any tufts, bristles etc. at tip of tail).
- T_a**: (*abbrev.*) ambient temperature; the temperature in which an animal is living. *cf.* T_b (*q.v.*).
- Ta**: ambient temperature; the temperature in which an animal is living. *cf.* T_b (*q.v.*).
- talonid**: heel at the posterior end of a lower molar tooth.
- tapetum lucidum**: light-reflecting layer behind or in the retina of the eyes of some vertebrates that reflects light back through the retina thereby increasing the sensitivity of the eye to dim light.
- taxon** (*pl.* **taxa**): any defined unit (e.g. family, genus, species, subspecies) in the classification of organisms.
- taxonomy**: the science of biological nomenclature; the study of the rules, principles and practice of naming and classifying species and other taxa. Sometimes considered as an integral part (and near synonym) of systematics (*q.v.*).
- T_b**: (*abbrev.*) body temperature; the temperature of the core (central) part of an animal. *cf.* T_a (*q.v.*).
- telocentric**: describes a chromosome that appears to have a terminal centromere (*q.v.*) and therefore only one arm. Modern studies have revealed that all chromosomes have two arms but the smaller arm of telocentric chromosomes is not visible under a light microscope.
- temporalis**: a broad radiating muscle arising from the coronoid process (*q.v.*) of the lower jaw and attaching to the upper part of the skull.
- termitarium** (*pl.* **termitaria**): a place where termites (Insecta: Isopoda) live. Often a large mound of modified hard soil. The shape and size of a termitarium is unique to each species of termite.
- terrestrial**: living on the ground. *cf.* arboreal (*q.v.*); scansorial (*q.v.*).
- territory**: an area defended by an individual against certain other members of the species, usually by overt aggression or advertisement; territory is marked by the urine, faeces or glandular secretions of the territory's owner. *cf.* home-range (*q.v.*).
- Tertiary Period**: geological period, 65–2 mya, comprising five epochs: Palaeocene, Eocene, Oligocene, Miocene and Pliocene (*q.v.*); followed by the Quaternary Period (*q.v.*).
- testes**: the male gonads, or testicles, in which spermatozoa are formed and in which the male hormone is produced.
- Tethys Sea**: the sea separating the two supercontinents, Gondwana (*q.v.*) and Laurasia (*q.v.*) during much of the Mesozoic Era before the opening of the Indian and Atlantic oceans during the Cretaceous Period (*q.v.*).
- thermal conductance**: a measure of the ability of substances (including pelage) to transfer heat.
- thermolability** (*adj.* **thermolabile**): the ability of a homeotherm (e.g. camel) to allow its body temperature to vary over a 24-hour period, without either hibernating or aestivating.
- thermoneutral zone**: the range of body temperatures within which an animal does not have to increase its metabolic rate to increase T_b (*q.v.*) (when T_a (*q.v.*) is low) and reduce T_b (when T_a is high).
- thermoregulation**: regulation of body temperature, either by metabolic or behavioural means (or both simultaneously) so that T_b (*q.v.*) is kept more or less constant.
- thoracic**: pertaining to, or situated upon, the chest.
- through-put time**: time taken for food to pass through the digestive tract.
- tibia** (*pl.* **tibiae**): one of the two bones forming the lower leg (the shin bone); part of hindlimb between knee and ankle.
- TL**: (*abbrev.*) total length from tip of snout to posterior end of tail. Equivalent to the head and body length and tail length added together. *See also* HB (*q.v.*) and T (*q.v.*).
- toothrow**: Generally, the row of teeth from the most anterior incisor tooth to the most posterior molar. In golden moles, the row of teeth from the canine to the most posterior molar. Sometimes used in contexts of specific types of teeth, e.g. premolar toothrow, molar toothrow.
- topotype**: any specimen from the type locality (*q.v.*), i.e. the same locality as that from which the holotype (*q.v.*) was taken.
- topotypical**: pertaining to the type locality (e.g. a topotypical population is one found at the type locality).
- torpor** (*adj.* **torpid**): a state in which there is a (usually short-term) reduction of metabolic rate and a lowering of T_b (*q.v.*) when T_a (*q.v.*) declines; arousal from torpor occurs when T_a increases and without high energy costs to the individual. Torpor is associated with a state of inactivity and reduced responsiveness to stimuli. Torpor lasts for only short periods of time (hours or days). *cf.* hibernation.
- tragus**: a cartilaginous structure, usually small, projecting from the inner side of the external ear just anterior to the auditory meatus (*q.v.*).
- transverse**: in a direction across the body from side to side. *cf.* longitudinal (*q.v.*).
- Triassic Period**: period (within the Mesozoic Era); 248–208 mya. The first mammals appeared in this period.

- triconid:** describes a molariform tooth having three cusps.
- tricuspid:** having three points or cusps (particularly of teeth).
- trifid:** divided into three by two emarginations (*q.v.*).
- tubercle:** a small rounded protuberance.
- tusks:** long, continuously growing incisor or canine teeth that protrude (usually in pairs) beyond the mouth in some mammals including elephants (in which the tusks are incisors), and warthogs and other pigs (in which the tusks are canines); comprised of dentine (ivory). Some mammals, e.g. hyraxes, have 'tusk-like' incisors.
- tympanic bulla** (*pl. tympanic bullae*): one of a pair of usually rounded bony capsules, on underside of skull (one on each side), housing structures of the middle and inner ear in many mammals. Also called auditory bulla (*q.v.*).
- type description:** the original description of a species; the original description of the holotype (and paratype[s] if included).
- type locality:** the locality from which a holotype (*q.v.*), lectotype (*q.v.*) or neotype (*q.v.*) was collected. Also called topotypical locality.
- type population:** the population from which the holotype was selected.
- type series:** the holotype and all specimens collected at the same place and time and used, together with the holotype, to describe a new species.
- type species:** usually the species that was the first to be described under the name of a new genus. Not all genera had a designated type species when they were first created; in such cases, other rules determine which species will be the type species.
- type specimen:** *see* holotype.
- underfur:** dense and often woolly layer of the pelage, situated close to the skin and below the soft hairs and guard hairs; usually short and present in those species that experience lower T_a .
- unicuspid:** having one cusp or point (particularly of teeth).
- upper critical temperature:** the highest ambient temperatures at which the animal must increase its metabolic rate to maintain a constant body temperature. If the ambient temperature increases above the upper critical temperature and the animal is unable to cool itself, it will enter hyperthermia and may eventually die. *cf.* lower critical temperature.
- uvula:** the conical projection from the posterior edge of the soft palate that plays a role in the articulation of sounds and the closing the nasopharynx during swallowing.
- vagility:** the ability to move about, disperse or migrate.
- vagrant:** an individual that has been found well outside the normal geographic range of its species, e.g. a bat or bird that has been wind-borne, or an animal that has been transported as a stowaway on a ship, to a distant locality.
- vascularized:** infiltrated with capillaries.
- vasoconstriction:** constriction of the capillaries of the blood system near the surface of the skin in order to reduce the rate of heat loss through the skin; a mechanism used by many mammals to conserve heat when T_a (*q.v.*) is low. *cf.* vasodilation (*q.v.*).
- vasodilation:** the dilation (or opening) of the capillaries of the blood system near the surface of the skin in order to increase the rate of heat loss through the skin; a mechanism used by many mammals to cool themselves when T_a (*q.v.*) is high. *cf.* vasoconstriction (*q.v.*).
- veld:** Afrikaans word, used mainly by southern African biologists, to refer to a wide variety of grassland vegetation types typically used for grazing. *See also* bushveld, highveld, lowveld.
- vertebra** (*pl. vertebrae*): any of the bones that make up the backbone.
- vertebral formula:** the number of vertebrae in each part of the spine, from anterior to posterior: the parts are cervical (C), thoracic (T), lumbar (L), sacral (S), caudal (Ca).
- vestigial:** small and imperfectly developed; a structure having a smaller and more simple form than the corresponding structure in an ancestral species.
- vibrissa** (*pl. vibrissae*): long stiff hairs on the face, especially around nostrils and lips; often associated with the perception of tactile sensation; 'whiskers'.
- vlei:** southern African term for a marsh or swamp, either permanent or seasonal.
- wadi:** a desert valley, usually dry at the surface except after heavy rainfall.
- water turnover:** the rate at which water (fluids) is utilized and replaced in the body per unit time (normally expressed as ml/kg body weight/day); the amount of water an animal processes through its body each day. Water turnover is related to water availability, the urine concentrating ability of the kidney, amount of protein in the diet and T_a (*q.v.*). Water turnover rates are characteristically low in arid-adapted mammals when compared with non arid-adapted mammals.
- West Africa:** ca. south of 18° N from Senegal to the Sanaga R. in Cameroon, and Bioko I. (Equatorial Guinea) (Rosevear 1965).
- WT:** (*abbrev.*) weight (mass) of an individual, usually expressed in grams (g) or kilograms (kg).
- xiphisternum:** The posterior segment, or extremity, of the sternum (sometimes called the xiphoid process).
- zalambdodont:** cheekteeth with three main cusps connected by crests (ectolophs) forming a V-shape; largest cusp is at the apex of the V (on the lingual or tongue side of the tooth); assumed to be derived from the primitive tribosphenic teeth found in some extinct early mammals. *cf.* dilambdodont (*q.v.*).
- ZW:** (*abbrev.*) *see* zygomatic width.
- zygomatic arch:** one of a pair of cheekbones, formed of the maxillary process anteriorly, jugal bone medially and squamosal bone posteriorly. Ranges from massive, broad, widely flared and bony, to frail, slender and cartilaginous. When present, provides protection to the eyes and orbits. Also called zygoma.
- zygomatic width (ZW):** greatest width between the outer aspect of one zygomatic arch to the equivalent position on the opposite zygomatic arch. *See also* GWS.

Series Acknowledgements

Jonathan Kingdon, David Happold, Thomas Butynski,

Michael Hoffmann, Meredith Happold and Jan Kalina

The editors wish to record their thanks to all the authors who have contributed to *Mammals of Africa* for their expert work and for their patience over the very protracted period that these volumes have taken to materialize. We also thank the numerous reviewers who have read and commented on earlier drafts of this work.

We are also grateful for the generosity of our sponsoring patrons, whose names are recorded on our title pages, who have made the publication of these volumes possible.

Special thanks are due to Andy Richford, the Publishing Editor at Academic Press, who initiated and supported our work on *Mammals of Africa*, from its inception up to the point where Bloomsbury Publishing assumed responsibility, and to Nigel Redman (Head of Natural History at Bloomsbury), David and Namrita Price-Goodfellow at D & N Publishing, and the whole production team who have brought this work to fruition. We also acknowledge, with thanks, Elaine Leek who copy-edited every volume. We are grateful to Chuck Crumly, formerly of Academic Press and now the University of California Press, for being our active advocate during difficult times.

We have benefited from the knowledge and assistance of scholars and staff at numerous museums, universities and other institutions all over the world. More detailed and personal acknowledgements follow from the editors of each volume.

The editors are also grateful to the coordinating team of the Global Mammal Assessment, an initiative of the International Union for Conservation of Nature (IUCN), which organized a series of workshops to review the taxonomy and current distribution maps for many species of African mammals. These workshops were hosted by the Zoological Society of London, Disney's Animal Kingdom, the Owston's Palm Civet Conservation Programme, and the Wildlife Conservation Research Unit at the University of Oxford; additionally, IUCN conducted a review of the maps for the large mammals by the Specialist Groups of the Species Survival Commission. We owe a particular word of thanks to all the staff and personnel who made these workshops possible, and to the participants who attended and provided their time and expertise to this important initiative. We also thank IUCN for permission to use data from the *IUCN Red List of Threatened Species*.

Acknowledgements for Volume VI

Jonathan Kingdon and Michael Hoffmann

The authors and editors of Volume VI would like to express their thanks and gratitude to the following people who kindly offered their time and expertise to help review species or higher-level profiles (or parts thereof), or who made available either published or unpublished information to authors or editors. The contributions, insights, advice and critiques of those listed below greatly improved the content and accuracy of individual profiles.

We ask forgiveness from anyone whose name is inadvertently omitted or misspelled. In particular, we owe a significant word of thanks to the late Rod East, former Chair of the IUCN SSC Antelope Specialist Group, who provided immensely useful advice on authors, reviewed several species profiles and provided much useful information. We also remember fondly the late Peter Grubb, whose advice on ungulate classification and taxonomy was indispensable. Sadly, besides Peter, we also lost Keith Eltringham, John Skinner and Vivian Wilson before this volume went to press. We hope that the final volume of *Mammals of Africa* serves as a monument to their contributions and to those of the many biologists before them.

Leus, Barbara Leuthold, Walter Leuthold, Rebecca Lewison, Eline Lorenzen, Gideon Louw, Callie Lynch, Alastair Macdonald, Chris Magin, Florence Magliocca, James Malcolm, David Mallon, Athol Marchant, John Mason, Erik Meijaard, Graham Mitchell, Patricia Moehلمان, Renata Molcanova, Steve Monfort, Yoshan Moodley, Michael Mooring, Dominic Moss, David Moyer, Wim Mullié, Souleye Ndiaye, John Newby, Helen Newing, Catherine Ngarachu, Bernhard Nievergelt, David Noble, Peter Novellie, William Oliver, Norman Owen-Smith, Ian Parker, Alexander Peal, Mike Perrin, Norbert Pfannenschmidt, Pierre Pfeffer, Djalle Pierre, Andy Plumptre, Gilfred Powys, Herbert Prins, Melvyn Quan, Wilhelm Räder, Befekadu Refera, Randy Reiches, Paul Reillo, Craig Roberts, Karen Ross, Francesco Rovero, Dave Rowe-Rowe, Ian Rushworth, Mostafa Saleh, Julia Salnicki, Dietrich Schaaf, Cathy Schloeder, Paul Scholte, Susanne Schultz, Erik Seiffert, Russell Seymour, David Shackleton, Steve Shurter, Kirstin Sixx, Claudio Sillero-Zubiri, Alberto Simonetta, Anthony R. E. Sinclair, the late John Skinner, Chris Smeenk, Jan Smielowski, Tommy Smith, Michael Somers, Clive Spinage, Mark Stanley Price, Emma Stokes, Tom Struhsaker, Chris Stuart, Tilde Stuart, Andrew Taylor, Ricky Taylor, the late Simon Thirgood, Kaci Thompson, Chris Thowless, Tom Thurow, Andrea Turkalo, Carlo Utzeri, Herman van Oeveren, Katja Vichl, Petri Viljoen, Fritz Volrath, Wolfgang von Richter, Tim Wachter, Alan Walker, Friedrich Wilhelmi, Stuart Williams, Doug Williamson, the late Vivian Wilson, Achim Winkler, Torsten Wronski, Piet Wit, Johannes Yagos, Derek Yalden, Alberto Zilli and Samuel Zschokke. A special word of thanks to Grant Hopcraft for permission to reproduce the map illustrating the Serengeti Wildebeest migration.

Through the first few formative years of the project, Mike Hoffmann was based in the University of Oxford's Wildlife Conservation Research Unit. This stay was made possible thanks to the efforts of the Commissioning Editor at Academic Press at the time, Dr Andy Richford, and the Director of WildCRU, Dr David Macdonald. Andy and David made it both financially and academically possible for me to move to the UK to join Jonathan on the *Mammals of Africa*. WildCRU further afforded access to the wonderful Bodleian library and that of the Edward Grey Institute, as well as to many like-minded African mammal researchers, several of them *Mammals of Africa* authors (including Andrew Loveridge, Stuart Williams and Claudio Sillero). Claudio became a particularly close and trusted friend, although it is only now that I realize what a novel influence he was. Subsequent to leaving WildCRU, and facilitated by a connection made by Tom

Butynski, I took up a position with Conservation International in Washington, DC., before transitioning into IUCN in 2006. I am particularly grateful to Tom Brooks, Russ Mittermeier and Simon Stuart, key supporters throughout my years at CI and IUCN, who made allowances for some of my time to be spent on *MoA* matters, and who cannot possibly know the profound inspiration that they have had on me personally as a conservationist. That I ever got involved in *Mammals of Africa* owes a great deal to the late John Skinner, my first mentor (with whom I jointly revised the 3rd edition of the *Mammals*

of the Southern African Subregion), for putting in a good word; Dick Estes, for suggesting I get in touch with Jonathan in the first place, and, of course, Jonathan himself, for putting his trust in such a novice as I was then. I look back now on the day Jonathan and I first met on 4 August 2000, and realize how far indeed we both have come. How proud I am to have had the privilege to work so closely with this giant of a man – this legend – and to call him my friend. And, finally, to my parents, for giving me the room to spread my wings, and giving me the courage to do so. To them, I owe everything.

Mammals of Africa: *An Introduction and Guide*

David Happold, Michael Hoffmann, Thomas Butynski and Jonathan Kingdon

Mammals of Africa is a series of six volumes that describes, in detail, every extant species of African land mammal that was recognized at the time the profiles were written (Table 1). This is the first time that such an extensive coverage has been attempted; all previous books and field guides have either been regional in coverage, or have described a selection of mammal species – usually the larger species. These volumes demonstrate the diversity of Africa's mammals, summarize what is known about the distribution, ecology, behaviour and conservation status of each species, and serve as a guide to identification.

Africa has changed greatly in recent decades because of increases in human populations, exploitation of natural resources, agricultural development and urban expansion. Throughout the continent, extensive areas of forest have been destroyed and much of the forest that remains is degraded and fragmented. Savanna habitats have been altered by felling of trees and development for agriculture. Many of the drier areas are threatened with desertification. As a result, the abundance and geographic ranges of many species of mammals have declined – some marginally, some catastrophically, some to extinction. Hence, it seems appropriate that our knowledge of each

species is recorded now, on a pan-African basis, because the next few decades will see even more human-induced changes. How such changes will affect each mammalian species is uncertain, but this series of volumes will act as a baseline for assessing future change.

The study of African mammals has taken several stages. During the era of European exploration and colonization, the scientific study of African mammals was largely descriptive. Specimens that were sent to museums were described and named. As more specimens became available, and from different parts of the Continent, there was increasing interest in distribution and abundance, and in the ecological and behavioural attributes of species and communities. At first, it was the largest and most easily observed species that were the focus of most studies, but as new methodologies and equipment became available, the smaller and more cryptic and secretive species became better known. Many species were studied because of their suspected role in diseases of humans and livestock, and because they were proven or potential 'pests' in agricultural systems. During the past decade or so, there has been greater emphasis on the genetic and molecular characteristics of species. All these studies have produced a wealth of information, especially during the past 40 years or so. These volumes are not only a distillation of the huge literature that now exists on African mammals, but also of much unpublished information.

Readers will notice that there is a huge discrepancy among species in the amount of information available. Some species have been studied extensively for many years, especially the so-called 'game species', some species of primates and a few species that are widespread and/or easily observed. In contrast, other species are known only by one or a few specimens, and almost nothing is known about them. Likewise, some areas and countries have been well studied, while other areas and countries have been neglected. During the preparation of these volumes, the editors have often been surprised by the wealth of information about some species when little was anticipated, and by the paucity of information about others, some of which were assumed to be 'well known'. In addition to presenting information that is based on sound scientific evidence, the aims of these volumes are to point out where there are gaps in knowledge and to correct inaccurate information that has become embedded in the literature. For most taxa, the detail provided in the species profiles allows accurate identification.

Mammals of Africa comprises six volumes (Table 2). The volumes consist mainly of species profiles – each profile being a detailed

Table 1. The mammals of Africa.

| Order | Number of families | Number of genera | Number of species |
|-----------------|--------------------|------------------|-------------------------|
| Hyracoidea | 1 | 3 | 5 |
| Proboscidea | 1 | 1 | 2 |
| Sirenia | 2 | 2 | 2 |
| Afrosoricida | 2 | 11 | 24 |
| Macroscelidea | 1 | 4 | 15 |
| Tubulidentata | 1 | 1 | 1 |
| Primates | 4 | 25 | 93 |
| Rodentia | 15 | 98 | 395 ^a |

Table 2. The six volumes of *Mammals of Africa*.

| Volume | Contents | Number of species | Editors |
|--------|--|-------------------|--|
| I | Introductory chapters. Afrotheria (Hyraxes, Elephants, Dugong, Manatee, Otter-shrews, Golden-moles, Sengis and Aardvark) | 49 | Jonathan Kingdon, David C. D. Happold, Michael Hoffmann, Thomas M. Butynski, Meredith Happold and Jan Kalina |
| II | Primates | 93 | Thomas M. Butynski, Jonathan Kingdon and Jan Kalina |
| III | Rodents, Hares and Rabbits | 408 | David C. D. Happold |
| IV | Hedgehogs, Shrews and Bats | 380 | Meredith Happold and David C. D. Happold |
| V | Carnivores, Pangolins, Equids and Rhinoceroses | 93 | Jonathan Kingdon and Michael Hoffmann |
| VI | Pigs, Hippopotamuses, Chevrotain, Giraffes, Deer and Bovids | 93 | Jonathan Kingdon and Michael Hoffmann |

account of the species. They have been edited by six editors who distributed their work according to the orders with which they were most familiar. Each editor chose authors who had extensive knowledge of the species (or higher taxon) and, preferably, had experience with the species in the field. Each volume follows the same general format with respect to arrangement, subheadings and contents. Because *Mammals of Africa* has contributions from 356 authors (each with a different background and speciality), and each volume was edited by one or more editors (each with a different perspective), it has not been possible or even desirable to ensure exact consistency throughout. Species profiles are not intended to be exhaustive literature reviews, partly for reasons of space. None the less, they are written and edited to be as comprehensive as possible, and to lead the reader to the most important literature for each species. Inevitably, not all information available could be accommodated for the better-known species, and so such profiles are a précis of available knowledge. Extensive references in the text alert the reader to more detailed information.

In addition to the species profiles, there are profiles for the higher taxa (genera, families, orders, and above). At the very least, there is a profile for each order, for each family within the order, for each genus within the family, and for each species within the genus. For some orders there are additional taxonomic levels, for example, subfamilies and tribes (Bovinae and Bovini, respectively). Species are presented according to phylogeny. The taxonomy used in these volumes mostly follows that presented in the third edition of *Mammal Species of the World: A Geographic and Taxonomic Reference* (Wilson & Reeder 2005), although authors have employed alternative taxonomies when there were good reasons for doing so. Volume I differs from the other volumes in that it contains a number of introductory chapters about Africa and its environment, and about African mammals in general.

The continent of Africa

For the purposes of this work, 'Africa' is defined as the continent of Africa (bounded by the Mediterranean Sea, the Atlantic Ocean, the Indian Ocean, the Red Sea and the Suez Canal) and the islands on the continental shelf that, at some time in their history, have been joined to the African continent. The largest of the 'continental islands' are Zanzibar (Unguja), Mafia and Bioko (Fernando Po). All 'oceanic islands', e.g. São Tomé, Príncipe, Annobón (Pagulu), Madagascar, Comoros, Seychelles, Mauritius, Socotra, Canaries, Madeira and Cape Verde are excluded, with the exception of Pemba, which is included because of its close proximity (ca. 50 km) to the mainland.

The names of the countries of Africa are taken from the *Times Atlas* (2005). The Republic of Congo is referred to as 'Congo' and the Democratic Republic of Congo (former Zaire) as 'DR Congo'. Smaller geographical or administrative areas within countries are rarely referred to except for Provinces in South Africa, which are used extensively in the literature. A political map of Africa, and of the Provinces of South Africa, is given (Figure 1), as well as a list of the 47 countries together with their previous names that are used in the older literature on African mammals (Table 3).

Africa is the second largest continent in the world (after Asia), but it differs from other continents (except Australia and Antarctica) in being essentially an island. At various times in the past, Africa has been joined to other continents – a situation that has had a strong influence on the fauna and flora of the continent. Africa is a vast continent (29,000,000 km², 11,200,000 mi²) that straddles the Equator, with about two-thirds of its area in the northern hemisphere and one-third in the southern hemisphere. As a result, Africa has many varied climates (with seasons in each hemisphere being 6 months out of phase), many habitats (including deserts, savannas, woodlands, swamps, rivers, lakes, moist forests, monsoon forests, mountains and glaciers), and altitudes ranging from 155 m (509 ft) below sea level at L. Assal, Djibouti, in the Danakil (Afar) Depression, to 5895 m (19,341 ft) on Mt Kilimanjaro, Tanzania. Africa is comprised of 47 countries, some of which are very large (e.g. Sudan [2,506,000 km²; 967,000 mi²], Algeria [2,382,000 km², 920,000 mi²] and Democratic Republic of Congo [2,345,000 km², 905,000 mi²]), and others that are relatively small (e.g. Djibouti [23,200 km², 9000 mi²], Swaziland [17,400 km², 6,700 mi²] and The Gambia [11,300 km², 4400 mi²]). The human population of each country also varies greatly, from about 346/km² in Rwanda to only about 2.5/km² in Namibia. With its great size and varied habitats, Africa supports a high biodiversity, including a large number of species of mammals. Likewise, most countries have a high diversity of mammals (especially when compared with temperate countries).

Africa may also be categorized into Biotic Zones (Figure 2). A biotic zone is defined as an area within which there is a similar environment (primarily rainfall and temperature) and vegetation, and which differs in these respects from other Biotic Zones. Africa can be divided into 13 Biotic Zones, two of which may be divided into smaller categories. The Biotic Zones concept provides a general assessment of the environmental conditions in which a species lives, as well as providing an assessment of the geographic distribution of the species. The Rainforest Biotic Zone and the South-West Arid Biotic Zone may be divided into regions and sub-regions that reflect the different biogeographical distributions of species, each region/

Figure 1. (a) Political map of Africa; (b) provinces of South Africa; (c) altitudes and major rivers of Africa. South Sudan and Somaliland are not identified as separate countries in the text.

Table 3. The countries of Africa: names, areas and human population density.

| Country name | Area
(km ²) '000 | Area
(miles ²) '000 | Human population
'000 (2006) | People per km ² |
|--|---------------------------------|------------------------------------|---------------------------------|----------------------------|
| Algeria | 2,382 | 920.0 | 33,500 | 14.1 |
| Angola (includes Cabinda) | 1,247 | 481.0 | 15,800 | 12.7 |
| Benin * [Dahomey] | 113 | 43.0 | 8,700 | 77.0 |
| Botswana [Bechuanaland] | 582 | 225.0 | 1,800 | 3.1 |
| Burkina Faso * [Upper Volta; Burkina] | 274 | 106.0 | 13,600 | 49.6 |
| Burundi [part of Ruanda-Urundi (= part of Belgian Congo)] | 27.8 | 10.7 | 7,800 | 280.5 |
| Cameroon [includes former French Cameroon, German Cameroon and part of Eastern Nigeria] | 475 | 184.0 | 17,300 | 36.2 |
| Central African Republic # | 623 | 241.0 | 4,300 | 6.9 |
| Chad [Tchad] | 1,284 | 496.0 | 10,000 | 5.8 |
| Congo [Republic of Congo] | 342 | 132.0 | 3,700 | 10.8 |
| Côte d'Ivoire * [Ivory Coast] | 322 | 125.0 | 19,700 | 61.2 |
| Democratic Republic of Congo [Belgian Congo; Congo (Kinshasha); Zaire] | 2,345 | 905.0 | 62,700 | 26.7 |
| Djibouti [French Somaliland] | 23.2 | 9.0 | 800 | 34.5 |
| Egypt | 1,001 | 387.0 | 75,400 | 75.3 |
| Equatorial Guinea # (includes Rio Muni [Spanish Guinea] and Bioko I. [Fernando Po]) | 28.1 | 10.8 | 500 | 17.8 |
| Eritrea (formerly part of Ethiopia) | 94 | 36.0 | 4,600 | 48.9 |
| Ethiopia [Abyssinia] | 1,128 | 436.0 | 74,800 | 66.3 |
| Gabon # | 268 | 103.0 | 1,400 | 5.2 |
| The Gambia | 11.3 | 4.4 | 1,500 | 132.7 |
| Ghana [Gold Coast] | 239 | 92.0 | 22,600 | 94.6 |
| Guinea * | 246 | 95.0 | 9,800 | 39.8 |
| Guinea-Bissau [Portuguese Guinea] | 36 | 13.9 | 1,400 | 38.9 |
| Kenya | 580 | 224.0 | 34,700 | 59.8 |
| Lesotho [Basutoland] | 30.4 | 11.7 | 1,800 | 59.2 |

| Mali * | 1,240 | 479.0 | 13,900 | 11.2 |
| Mauritania * | 1,030 | 412.0 | 3,200 | 3.1 |
| Morocco [includes former Spanish Morocco and French Morocco; (now also includes Western Sahara = former Spanish Sahara)] | 447 | 172.0 | 32,100 | 71.8 |
| Mozambique [Portuguese East Africa] | 802 | 309.0 | 19,900 | 24.8 |
| Namibia [South-west Africa] | 825 | 318.0 | 2,100 | 2.5 |
| Niger * | 1,267 | 489.0 | 14,400 | 11.3 |
| Nigeria | 924 | 357.0 | 134,500 | 145.6 |
| Rwanda [part of Ruanda-Urundi (= part of Belgian Congo)] | 26.3 | 10.2 | 9,100 | 346.0 |
| Senegal * | 197 | 76.0 | 11,900 | 60.4 |
| Sierra Leone | 71.7 | 27.7 | 5,700 | 79.5 |
| Somalia* [British Somaliland and Italian Somaliland; Somali Republic] | 638 | 246.0 | 8,900 | 13.9 |
| South Africa | 1,220 | 471.0 | 47,300 | 38.7 |
| Sudan § [Anglo-Egyptian Sudan] | 2,506 | 967.0 | 41,200 | 16.4 |
| Swaziland | 17.4 | 6.7 | 1,100 | 63.2 |
| Tanzania [German East Africa; Tanganyika] (now includes Zanzibar I., Mafia I. and Pemba I.) | 945 | 365.0 | 37,900 | 40.1 |
| Togo [Togoland] | 56.8 | 21.9 | 6,300 | 110.9 |
| Tunisia | 164 | 63.0 | 10,100 | 61.6 |
| Uganda | 236 | 91.0 | 27,700 | 117.4 |
| Zambia [Northern Rhodesia] | 753 | 291.0 | 11,900 | 15.8 |
| Zimbabwe [Southern Rhodesia] | 391 | 151.0 | 13,100 | 33.5 |
| Totals/mean density | 29,448 | 11,383 | 902,600 | 56.8 |

Former names are listed in chronological order in square brackets, with the oldest name listed first. Obsolete names are listed because much of the older literature refers to past colonial entities. * = formerly part of French West Africa. # = formerly part of French Equatorial Africa. § At the time of going to press, the country of Sudan had been divided into two: the Republic of Sudan in the north, and the Republic of South Sudan in the south. *The former British Somaliland is now a self-declared state under the name of the Republic of Somaliland, but remains internationally unrecognized.

The pigs, hippopotamuses, chevrotain, giraffes, deer and bovids of Africa

This volume, Volume VI, is devoted to the order Cetartiodactyla, a large order that unites the traditional 'artiodactyls' (even-toed ungulates) with the whales and dolphins. The order includes three main subdivisions: Suiformes (pigs); Whippomorpha (hippopotamuses, whales and dolphins); and Ruminantia (including the chevrotain, giraffe and okapi, deer and the bovids). In total, the order includes 98 species (treated in 93 species profiles), although the majority comprise the antelopes, which have radiated into a remarkable 76 species in 12 different tribes. A single species of African cetartiodactyl, the Bluebuck *Hippotragus leucophaeus*, is documented as having become extinct since 1500 (though many are teetering on the brink) and is discussed briefly under the genus account, but is otherwise not treated separately. Introduced species are mentioned in the higher-level profiles (where relevant), but are not otherwise profiled.

At the time of going to press, a new species of duiker in the genus *Philantomba* had been described, *Philantomba walteri* (Colyn *et al.* 2010). Unfortunately, it was not possible to include an individual species profile, but we provide general characteristics that distinguish this new species under the genus profile. Details on the type locality description follow (see also the *Philantomba* genus profile).

Walter's Duiker *Philantomba walteri* Colyn, Hulselmans, Sonet, Oudé, de Winter, Natta, Nagy & Verheyen, 2010. Igberé (08° 59' N 01° 57' E), Forêt Protégée de Wari-Marou (328 m altitude), near the Ecological Center of Manigri, Benin.

As *Mammals of Africa* was being finalized, a new work by Colin Groves and the late Peter Grubb, *Ungulate Taxonomy*, was published but it has not been possible to fully consider and evaluate the conclusions and classification presented in that work.

Figure 2. The biotic zones of Africa. The numbers refer to the biotic zones as described in the text.

sub-region having a community of mammals and other animals which is different to any other. Details of the Biotic Zones of Africa, and the regions and sub-regions of the Rainforest Biotic Zone and South-West Arid Biotic Zone, are given in Volume I of *Mammals of Africa*.

Figure 4. External features of a mammal: *Genetta* sp. (side-view and face frontal).

Species profiles

Information about each species is given under a series of subheadings. The amount of information under each of these subheadings varies greatly between species; where no information is available, this is recorded as 'No information available' or words to this effect. The sequence of subheadings is as follows:

Scientific name (genus and species) The currently accepted name of the species.

Vernacular names English, French and German names are given, as available. The first given English name is the preferred vernacular name for the species; alternative names are given in parentheses for some species. Wilson & Cole (2000) list proposed vernacular names for all the world's mammals; most of these names were also given in the third edition of *Mammal Species of the World* (Wilson & Reeder 2005). Although these works have been consulted, the names used have not always been adopted in *Mammals of Africa*. French and German names were usually provided by authors.

Scientific Citation This provides the full scientific name of the species, i.e. genus name, species name, authority name, and date of authority. Parentheses around the authority's name and date indicate that the species was originally named in a different genus to its present generic allocation. The scientific name is followed by the publication where the species was described, and the location where the type specimen (or type series) was obtained. Most of this information is taken from Wilson & Reeder (2005).

Taxonomy This section contains information on taxonomic problems, if any, associated with the species, and its relationship with other species in the genus. For some species, there is considerable information about these topics; for others, there may be nothing. A list of synonyms (without the taxonomic authority for each) and the number of subspecies (if any) is presented, mostly taken from Wilson & Reeder (2005). The chromosome number is given if available, and in some cases this is followed by other information relevant to the chromosomes.

Description This section, together with the illustrations, provides the reader with adequate information to identify the species. The section begins with a brief overall description of the species, including an indication of size. This is followed by a detailed description of the external features of the species' head (and parts of the head), dorsal pelage, legs, feet, ventral pelage, and tail (in this order), as well as any special characteristics unique to the species. For some species, diagnostic characteristics of the skull and dentition are given, and for bovids the horns. This section may also present information on ageing criteria, where this has been investigated with some degree of rigour. The characters described in this section are common to all subspecies of this species (unless otherwise noted). The mammary formula, i.e. the number and arrangement of nipples in adult females, is noted wherever this feature varies between the taxa being discussed.

Geographic Variation Variation within the species may be of two sorts: (a) clinal variation without subspecies, or (b) subspecific variation. If (a), there is a description of the character(s) that alter clinally across the geographic range of the species. If (b), each of the subspecies is listed with its geographic range and, where available,

the characters that distinguish it from other subspecies of the species. For some species, subspecies have been described that are no longer considered to be valid; in some cases, such names may be listed but without further comment.

Similar Species Species that are sympatric or parapatric with the species under consideration, and with which it may be confused, are listed along with diagnostic characteristics (additionally, readers may refer to profiles of the similar species in question). In some instances, species that are allopatric in distribution are also included.

Distribution The first sentence ‘Endemic to Africa’ informs the reader that this is an African species and does not occur on any other continent; if a species also occurs outside Africa, this is noted at the end of this section with a very brief synopsis of the extralimital range. The distributions of the cetartiodactyls are among the best studied and well documented of African mammals, and the monumental work of Rod East (1999), complemented by subsequent updates from the IUCN SSC Antelope Specialist Group, provides an unrivalled platform for detailing the ranges of most species. For widespread species that generally remain so today (e.g. *Sylvicapra grimmia*), the text provides a general idea of the range, highlighting only places or countries where the species may have been extirpated, recently newly recorded, or providing clarity on previously incorrectly attributed country records and range limits. In the case of widespread species that have undergone significant range contractions and declines (e.g. *Addax nasomaculatus*), the text generally differentiates between former and current ranges in an attempt to elucidate a clearer picture of where species do, or no longer, occur. Finally, for more range-restricted species (e.g. *Beatragus hunteri*), the information provided may be quite precise, detailing even localized distribution within the confines of its small range. For species with recognized and well-differentiated subspecies, we have attempted to present the details of the distributions accordingly, and within the framework presented above. Although great effort has been expended in ensuring this section is current and provides a true picture of the current range of the species, many data gaps remain, especially for parts of North and West Africa, Sudan, Somalia, parts of DR Congo, Angola and Mozambique. A distribution map (see below) augments the information given here.

Habitat This section provides a description of the range of habitats where the species lives. Details of plant communities, plant species, vegetation structure, soil type and/or structure, and water availability, etc. (if available) are also recorded. Other information may include average annual rainfall, altitudinal limits, and seasonal variation in habitat characteristics.

Abundance A general indication of abundance in the habitat. This may be unquantified, such as abundant, common, uncommon, rare, or phrases such as ‘rarely seen but frequently heard’, etc. For better-known species, abundance may be expressed as estimates of density (e.g. number/ha or number/km²) as well as in terms of actual numbers of individuals for the species. Other information may include seasonal changes in density, frequency of observations, or the relative abundance of specimens in collections.

Adaptations This section describes morphological, physiological and behavioural characteristics, which show how the species uniquely interacts with its environment, conspecifics and other animals. This section may also describe species-specific adaptations for feeding, locomotion, burrowing, mechanisms for orientation, production of sound, sensory mechanisms and activity patterns. In some instances comparison with related or convergent species allows the unique adaptations of the species under discussion to be detailed or highlighted.

Foraging and Food This section provides information on the diet and foraging habits of the species. The diet is described either by a list of the taxa of animals or plants consumed, or as a quantitative measure of the contents of the stomach or the faeces. This section can also include any of the following: location of food, foraging behaviour, times when foraging occurs and daily distance moved; hoarding; seasonal changes in diet and food availability; individual or cooperative behaviour used in foraging and hunting; sex and age differences in foraging and diet; and nomadic or migratory movements in relation to food availability.

Social and Reproductive Behaviour Topics in this section may include group structure (whether solitary, social, or colonial), group size and composition; agonistic and amicable behaviour, comfort behaviour, etc.; home-range (including quantitative data), territorial behaviour, courtship and mating behaviour, behaviour of young, parental–young interactions; presence of helpers, vocalizations, and interactions with other species (mammals, birds, etc.).

Reproduction and Population Structure This section begins with an assessment of reproductive strategy (if known) and the times/seasons of the year when individuals are reproductively active (pregnancy and lactation in females, active spermatogenesis in males). Other information may include length of gestation, times/seasons of births, including peaks of births, litter-size, birth-weight and size, spacing of litters, growth and time to weaning, maturity, longevity, and mortality rates. Reproductive strategies, if known, are described with respect to locality, food availability and population density. Population structure (sex ratio, adult/young ratio, abundance of different cohorts in the population at different times of the year) may be described, and related to seasonal variations in reproduction and environmental variables.

Predators, Parasites and Diseases The known predators, parasites and diseases are listed. Information on parasites and diseases is not intended to be exhaustive, but simply to provide an entry point into the literature on the topic. In some cases, information on diseases from captive animals is presented. Additional information is given if the species is a host to diseases that affect humans and domestic stock.

Conservation The conservation status of the species is stated, as given by the *IUCN Red List of Threatened Species* (version 2011.2). The IUCN Red List categories follow the definitions and criteria given in the *IUCN Red List Categories and Criteria Version 3.1* (Table 4). For those species classified as threatened (i.e. ‘Vulnerable’,

Table 4. IUCN Red List Categories (from IUCN – International Union for Conservation of Nature).

| Category | Description |
|-----------------------------------|--|
| Extinct (EX) | A taxon is Extinct when there is no reasonable doubt that the last individual has died. A taxon is presumed Extinct when exhaustive surveys in known and/or expected habitat, at appropriate times (diurnal, seasonal, annual), throughout its historic range have failed to record an individual. Surveys should be over a time frame appropriate to the taxon's life-cycles and life-form. |
| Extinct in the Wild (EW) | A taxon is Extinct in the Wild when it is known only to survive in cultivation, in captivity or as a naturalized population (or populations) well outside the past range. A taxon is presumed Extinct in the Wild when exhaustive surveys in known and/or expected habitat, at appropriate times (diurnal, seasonal, annual), throughout its historic range have failed to record an individual. Surveys should be over a time frame appropriate to the taxon's life-cycle and life-form. |
| Critically Endangered (CR) | A taxon is Critically Endangered when the best available evidence indicates that it meets any of the criteria A to E for Critically Endangered, and it is therefore considered to be facing an extremely high risk of extinction in the wild. |
| Endangered (EN) | A taxon is Endangered when the best available evidence indicates that it meets any of the criteria A to E for Endangered, and it is therefore considered to be facing a very high risk of extinction in the wild. |
| Vulnerable (VU) | A taxon is Vulnerable when the best available evidence indicates that it meets any of the criteria A to E for Vulnerable, and it is therefore considered to be facing a high risk of extinction in the wild. |
| Near Threatened (NT) | A taxon is Near Threatened when it has been evaluated against the criteria but does not qualify for Critically Endangered, Endangered or Vulnerable now, but is close to qualifying for (or is likely to qualify for) a threatened category in the near future. |
| Least Concern (LC) | A taxon is Least Concern when it has been evaluated against the criteria and does not qualify for the Critically Endangered, Endangered, Vulnerable or Near Threatened categories. Widespread and abundant taxa are included in this category. |
| Data Deficient (DD) | A taxon is Data Deficient when there is inadequate information to make a direct, or indirect, assessment of its risk of extinction based on its distribution and/or population status. Data Deficient is not a category of threat. Listing of taxa in this category indicates that more information is required and acknowledges the possibility that future research will show that a threatened classification is appropriate. |
| Not Evaluated (NE) | A taxon is Not Evaluated when it has not yet been evaluated against the criteria. |

'Endangered', 'Critically Endangered'), the criteria met are also indicated. Some species have changed status due to improved knowledge, taxonomic revision, or the impact of threatening processes or conservation actions. Readers can obtain detailed reasons for the past and present status of a species by going to the IUCN Red List website (www.iucnredlist.org). If a species was listed on Appendix I, II or III under CITES (Convention on International Trade in Endangered Species – www.cites.org – as of 22 December 2011) or Appendix I or II of CMS (Convention on Migratory Species – www.cms.int – as of 5 March 2009) this is also indicated. For some species, additional information is provided, such as presence in protected areas, major threats, and current or recommended conservation measures.

Measurements A series of morphological measurements is provided. For each species there is a standard set of measurements. The abbreviations for each measurement are given in the Glossary. A measurement is cited as the mean value (with minimum value to maximum value in parentheses), and sample size. For some, the standard deviation (mean \pm 1 S.D.) is given instead of the range. Where possible, data for males and females are presented separately. In some cases, more than a single set of measurements is given; this is particularly the case for widespread species where geographic variation in size may be evident, and also for species with several well differentiated subspecies (in which case, we have endeavoured to present a set of measurements for each). Some species have additional stand-alone measurements presented beneath the primary series. Skull measurements generally are not provided; however, in the case of the antelopes, maximum recorded horn length (and the location of this record) based on the Rowland Ward (27th edition) measuring system is indicated. The majority of measurements also contain the location(s) where the specimens were obtained, and the source of the

data. Sources are either cited publications, or specimens in museums, or unpublished information from authors or others. The acronyms for museums where specimens were examined and measured are given in Table 5.

Key References A select list of references, which provides more general information on the species, or is generally considered as a key reference work on the species. Each reference is given in full in the Bibliography. Citations given in the text (but not cited in 'Key References') are also given in full in the Bibliography. In general, profiles account for all literature published up until the end of 2007. Authors and editors have endeavoured to keep the species profiles up-to-date throughout the long production schedule, and references published from 2008 onwards have been incorporated wherever possible. None the less, certain key recent papers will have been missed or omitted.

Author The name of the author, or authors, is given at the end of each profile. All profiles should be cited using the author name(s).

Tables With one or two exceptions, the use of tables to present data has been avoided in this volume of *Mammals of Africa*.

Table 5. Museum acronyms.

| Acronym | Museum name |
|---------|--|
| AMNH | American Museum of Natural History, New York, USA |
| BMNH | Natural History Museum, London, UK [formerly British Museum (Natural History)] |
| MRAC | Musée Royal de l'Afrique Centrale, Tervuren, Belgium |
| NMK | National Museums of Kenya, Nairobi, Kenya |
| PCM | Powell-Cotton Museum, Birchington, UK |

Higher taxon profiles

The profiles for orders, families and genera are internationally much less structured than for the species profiles. Each profile usually begins with a listing of the taxa in the next lower taxon; for example, each family profile lists the genera in that family. An exception to this arrangement is where a taxon has only one lower taxon. Higher taxa profiles provide the characteristics common to all members of that taxon. Some of these characteristics (for example, number of nipples or dental formula) may not be repeated in lower taxon profiles (unless essential for identification), so readers are encouraged to consult also the higher-taxa profiles, e.g. the species profile for *Raphicerus campestris* should be consulted in association with the genus *Raphicerus* and the tribe *Raphicerini* profile.

Distribution maps

Each species profile contains a pan-African map showing the geographic range of the species. In the case of the antelopes, the maps draw heavily on the publications of East (1988–1990, 1999), subsequent ASG updates and recent survey reports (e.g. Fay *et al.* 2007 for southern Sudan). The purpose of the maps is to show current known limits of distribution of the species within historical range, recognizing that within this mapped range a particular species' distribution will not be homogeneous. In general, reintroductions within the former range of a species are included and mapped (unless otherwise indicated), but introductions outside of the former known range are not. Even applying these rules, mapping current distributions in some parts of the continent, and especially in southern Africa where the game ranching industry has resulted in major faunistic shufflings, has proved very complicated. After much consideration, it was decided not to map historical ranges for species, given the difficulty in mapping these with any level of accuracy for a number of species, differing concepts on what 'historical' means, and the availability of such maps in other sources (e.g. Sidney 1965, Du Plessis 1969). However, in the absence of more recent and reliable information for some countries (especially Angola, Mozambique, Somalia and so forth), the range maps may actually reflect historical distributions far better than they do current range. Subspecies are

only indicated in cases where the boundaries can be reasonably delineated.

Each map shows the boundaries of the 47 countries of Africa, some of the major rivers (Nile, Niger–Benue, Congo [with the tributaries Ubangi, Lualaba and Lomani], Zambezi and Orange), and Lakes Chad, Tana, Turkana (formerly Rudolf), Albert, Edward, Victoria, Kyoga, Kivu, Tanganyika, Malawi, Mweru, Bangwuela and Kariba. The map projection is Transverse Mercator, with the following parameters: False Easting: 0; False Northing: 0; Central Meridian: 20; Linear Unit: metre; Datum: Clarke 1866.

The geographic distribution of a species is indicated as:

- red shading = current range. Different colour shading denotes subspecies, where appropriate.
- × = isolated locations considered to be separate from the main geographic range(s); some locations indicated by × may include two or more closely spaced locations.
- ? = uncertain, but possible, presence.
- red arrow = recorded from the island indicated by the arrow.

Cetartiodactyla, of which 98 terrestrial species occur in Africa, are commonly referred to as the ‘even-toed ungulates’ or Artiodactyla. This placental order contains pigs (suborder Suiformes), camelids (suborder Tylopoda; extralimital to Africa), ruminants (suborder Ruminantia) and the hippopotamuses (hereafter hippos), the latter of which now comprise the suborder Whippomorpha together with the whales and dolphins. The distinctness as well as the relatedness of each of these taxa is now well supported by molecular and genomic data. The etymology of this new taxon therefore combines the two traditional orders ‘Artiodactyla’ and ‘Cetacea’ into an enlarged order ‘Cetartiodactyla’.

Traditional taxonomy, based on morphology, placed whales in their own order, Cetacea, but over the course of the last decade a steady accumulation of nucleotide sequence data and other genomic information has made it clear that whales are actually deeply nested within the ‘artiodactyl’ radiation as the sister-group of Hippopotamidae (e.g. Gatesy *et al.* 1996, Nikaido *et al.* 1999, Murphy *et al.* 2001, Amrine-Madsen *et al.* 2003, Arnason *et al.* 2004, Meredith *et al.* 2011, Hassanin *et al.* 2012). This hypothesis has since come to be supported by phylogenetic analyses of morphological data from living and extinct cetartiodactyls (Geisler & Uhen 2003, 2005), as well as combined molecular-morphological analyses of the order (Spaulding *et al.* 2009). It has been argued that the taxon Artiodactyla should be retained for this assemblage (Archibald 2003, Asher & Helgen 2010), but this practice threatens to engender considerable confusion among specialists, because some workers have used the taxa Cetartiodactyla and Artiodactyla in order to express their recognition of a sister-taxon relationship between a monophyletic Cetacea and a monophyletic Artiodactyla (e.g. Thewissen *et al.* 2001). Relationships among the major cetartiodactyl clades are a matter of ongoing debate, and estimates of cetartiodactyl phylogeny have generated an extensive literature (Gatesy *et al.* 1999, 2002, Nikaido *et al.* 1999, Matthee *et al.* 2001, Murphy *et al.* 2001, Arnason *et al.* 2004, Geisler & Uhen 2005, Spaulding *et al.* 2009, Meredith *et al.* 2011, Hassanin *et al.* 2012).

One of the first responses to the molecular evidence supporting the placement of whales within Artiodactyla was to re-examine artiodactyls and cetaceans, both extant and fossil, to seek morphological evidence for or against this unexpected affinity (Luckett & Hong 1998). In spite of continued scepticism, living and extinct cetartiodactyls can now be recognized on the basis of at least three distinctive postcranial

Astragalus of extinct hippopotamus (from Kingdon 1982).

and dental features: (1) the head of the astragalus is trochlear, leading to the characteristic ‘double-pulley’ shape; (2) manus and pes are paraxonic, which means that the weight-bearing axis passes through digits III and IV (metapodials III and IV have become elongate and thickened, whereas metapodials II and V have been reduced in length and diameter, and digit I has been greatly reduced or lost entirely); and (3) the deciduous fourth premolar (p4) is distinctly trilobed, and the anterior lobe occludes between the outer (paracone and metacone) cusps of the upper deciduous third premolar (p³). The molariform p4 is later replaced by a premolariform p4. Until recently, the astragalar and pedal morphology of primitive cetaceans was not known; however, it is now clear that the archaeocetes *Pakicetus*, *Ichthyolestes*, *Rodhocetus* and *Artioclavus* all had double-pulley astragali (Gingerich *et al.* 2001, Thewissen *et al.* 2001), and *Rodhocetus* had a paraxonic arrangement of the pedal digits (Gingerich *et al.* 2001).

Molecular estimates for the origin of crown Cetartiodactyla extend back to near the K–T (Cretaceous–Tertiary) boundary (Springer *et al.* 2003, Meredith *et al.* 2011), but the group is not known in the fossil record before the earliest Eocene, around 55 mya. The most generalized cetartiodactyl is arguably *Diacodexis* (sometimes called ‘*Gujaratia*’) *pakistanensis*, from the early Eocene of Pakistan (Thewissen & Hussain 1990, Geisler & Uhen 2005). *Diacodexis* appears to have migrated out of Asia into Europe and North America during a brief period of intense global warming at the Palaeocene–Eocene boundary, and thereafter primitive cetartiodactyls (many of which are now of unclear phylogenetic position) are known from all three northern continents, and with time become common members of Laurasian mammal faunas. Recognizable stem or crown members of the Ruminantia, Tylopoda and Suiformes do not appear until much later in the Palaeogene, but all are ultimately of Laurasian origin. The presumably semi-aquatic anthracotheriid artiodactyls first appear in Africa in the late Eocene (Holroyd *et al.* 1996); otherwise, fully terrestrial cetartiodactyls are not known in Africa before the early Miocene.

Details of taxonomy and biology among the very diverse cetartiodactyls are discussed under appropriate taxonomic profiles,

but it is difficult to overstate the revolution in biological thinking that has accompanied these molecular discoveries. While earlier scenarios had, for example, suggested that whale ancestors were terrestrial carnivores, more recent discoveries make larger, more omnivorous,

and perhaps superficially pig-like ancestors more likely (Thewissen *et al.* 2007). Reconstructing the earliest history of whale evolution now presents new challenges and an added impetus for scientists to find still earlier proto-whale fossils. Among the challenges will be the plausible reconstruction of sequences and successions of feeding styles between ancient terrestrial artiodactyls and today's fish, squid and krill-eating whales.

Interpolation of purely herbivorous hippopotami into the whales' ancestral tree has brought many new dimensions to study of the Cetartiodactyla, but in spite of the challenges and new uncertainties, one thing remains unchanged, and Dawkins (1996) put it this way: 'there is no doubt that whales and dugongs come with their dry-land history written all over them. If they had been deliberately created for the sea, they'd be very different, and a lot more like fish than they are. Animals that have their history written all over them are among the most graphic pieces of evidence we have that living things were not created for their present ways of life but evolved from very different ancestors' (p. 133).

Modern genetics has forced us to examine hippos with more open minds and eyes. When we get to re-examine other Cetartiodactyla with similar intensity we will find that antelopes, giraffes and others will also have their history written all over them, even if in subtler phrases.

Tentative phylogenetic tree for Cetartiodactyla (after Bininda-Emonds *et al.* 2007 and Hassanin *et al.* 2012).

Suborder SUIFORMES – Pigs

Suiformes Jaekel, 1911. Die wirbeltiere: eine übersicht über die fossilen und lebenden formen, Berlin. pp. 233.

Traditionally, the Suiformes have been viewed as a clade that included not only the African pigs and hippos, and their extant and extinct Eurasian relatives, but also forms with no known living counterparts, such as the Anoplotheriidae from Europe, the Raoellidae from Asia, the Choeropotamidae from Eurasia and the Oreodontoidea from North America, plus the Dichobunoidea, Anthracotheroidea and Entelodontoidea that are known from both Eurasia and North America (McKenna & Bell 1997). Recent advances in our understanding at the molecular level of artiodactyl evolution, together with new and complete Palaeogene whale fossils and reinterpretation of previously documented fossil evidence, have led to the recognition of the order Cetartiodactyla in which ancodonts (anthracotheres and hippos) are now grouped with cetaceans (whales and dolphins) in the suborder Whippomorpha, whereas pigs and peccaries are retained in the suborder Suiformes.

The Suiformes are today represented in Africa by four genera of the family Suidae, which is in turn grouped with the extralimital peccaries (Tayassuidae) and extinct sanitheres (Sanitheriidae) into the superfamily Suoidea. The Suoidea are united by the uniquely derived features (autapomorphies) of: lack of a lingual cingulum on the upper molars; the similarity of the lower first and second incisors; a rootless lower male canine; paraconid fused to metaconid in the lower cheekteeth; tympanic process of squamosal dorsoventrally elongate and external auditory meatus opening dorsally; and by the presence of ossified tympanic bullae (Liu 2003).

The sister relationship between Suidae and Tayassuidae is well documented on both morphological (Gentry & Hooker 1988) and molecular grounds (Irwin & Arnason 1994, Randi *et al.* 1996). Pigs and peccaries occupy similar adaptive zones (*sensu* Simpson 1944) in the Old and New World, respectively. Both are primarily omnivorous and of the living artiodactyls display the most primitive traits – retaining four distinct digits, separated foot bones, absence of frontal appendages, a simple, non-ruminating stomach, and the less progressive forms having low-crowned cheekteeth with simple bunodont cusps. Sanitheres cheekteeth are bunoselenodont, with a tendency to further complicate the premolars by polycuspy and polycristy accompanied by heavy wrinkling of occlusal enamel. In some dental and cranial features the sanitheres are convergent on selenodont artiodactyls, but the astragalus is characteristically suoid (Pickford 1984).

The oldest suoid fossils now known are from the late Eocene of China (Tong & Zhao 1986, Liu 2001) and Thailand (Ducrocq 1994, Ducrocq *et al.* 1998). Although the evidence is still sparse and incomplete, it would appear that suoids originated in eastern Asia during the Eocene, subsequently dispersing into the New World (Tayassuidae) and elsewhere in the Old World (Suidae) during the Oligocene (Ducrocq 1994, Ducrocq *et al.* 1998, Liu 2001).

Phylogenetic tree of extant African suidae (modified after White & Harris 1977 and Hassanin *et al.* 2012).

The family Suidae contains the pigs and their relatives. Suids are robust animals with relatively short legs and large heads. The modern forms have a short braincase and an exceedingly elongated facial skeleton forming a tubular snout. Peculiarly characteristic of suids among African ungulates is the terminal position of the nostrils, surrounded by a partly cartilaginous, mobile disc attached to a central prenasal bone; they have leathery, sometimes sparsely haired skin. All pigs have simple stomachs, lacking the fermentation chambers of ruminants.

Suidae are separated from other suoids by the absence of the angular process of the mandible (Liu 2003). Suid molars are also characterized by the presence of three furrows or 'furchen' on each of the four main cusps (Hünemann 1968, Pickford 1986), a feature that is lacking in the bunodont peccaries and bunoselenodont sanitheres. This furrowed enamel is thrown into subsidiary cusps surrounding the main cusps. Suids have developed a diastema between the canine 'tusks' and the masticatory tooththrow with progressive reduction of the premolars in grass-eating species. This trend can be

correlated with improved milling of tough vegetation and finds its most extreme expression in the warthogs *Phacochoerus* spp. where mature individuals only retain M3. The mesial premolars are small and unicuspid, but the premolar and molar series gets progressively more complex distally, with the third molars capable of elongation with three or more pairs of cusps. The upper incisors are small and spaced, the lowers somewhat procumbent. The upper canines are small and pointed in the ♀, large and curved outward and upward in the ♂, and form potent weapons.

The Suidae have been divided into several subfamilies. The Listriodontinae are characteristic of the early to middle Miocene (21–14 mya) in Eurasia and Africa; early forms had low-crowned bunodont teeth but more advanced representatives developed tapir-like lophodont molars. The Kubanochoerinae had a similar temporal and geographic range to the listriodontines; they retained low-crowned bunodont teeth, but some species developed horns on the frontal and above the orbits. Tetraconodontines were most abundant in the late Miocene and Pliocene (9–4 mya) of Africa and Asia and developed very large third and fourth premolars. The Namachoerinae were precociously lophodont, short-snouted suids from the early to mid-Miocene of Africa. Cainochoerines were pygmy forms from the late Miocene of eastern and southern Africa. The bunodont *Palaeochoerus* of Europe (Oligocene to early Miocene, 34–22 mya) was at one time interpreted as an 'Old World peccary', but Liu (2003) reinterpreted it as part of an unresolved stem group of the Suoidea. The lophodont Schizotheriinae of the African and Eurasian Miocene were also interpreted as 'Old World peccaries', but Liu (2003) included them in the Suidae.

The extant suids are sometimes interpreted as representing three subfamilies: Suinae (widely distributed in the Old World), Phacochoerinae (sub-Saharan Africa) and Babyrousinae (eastern Asia), but their similarities to each other, and differences from extinct suid subfamilies, probably only warrants separation at the tribal level (which is the approach followed herein).

Colin Groves & John M. Harris

Subfamily SUINAE – Pigs, Hogs

Suinae Gray, 1821. London Med. Repos. 15: 306.

The first representatives of the Suinae appeared towards the end of the middle Miocene in Europe and Asia. Suinae crania are distinguished by an elongated flange – the prezygomatic shelf – that projects anteriorly from the zygomatic root. This flange separates the chewing musculature from the muscles that operate the snout. It was not present in the hyotheriines, kubanochoeres, listriodonts and tetraconodonts, where the anterior tendinal guides for the snout musculature in the vicinity of the canines were generally poorly developed. This suggested to Pickford (1993) that the characteristic

rooting habit of extant pigs is restricted to the Suinae. Another progressive feature of suines is the development of sagittal cusplets between the labial and lingual cusps of the upper fourth premolar.

The Suinae radiated rapidly and are represented by some 15 genera during and after the late Miocene. The heterogeneous nature of suine molars could permit these pigs to be treated as a subfamily, which could be further subdivided into several component tribes, but there is currently little consensus of opinion as to tribal compositions. However, there is general recognition that the hypsodont African

suines (*Phacochoerus* and the extinct *Metridiochoerus*) form a natural grouping.

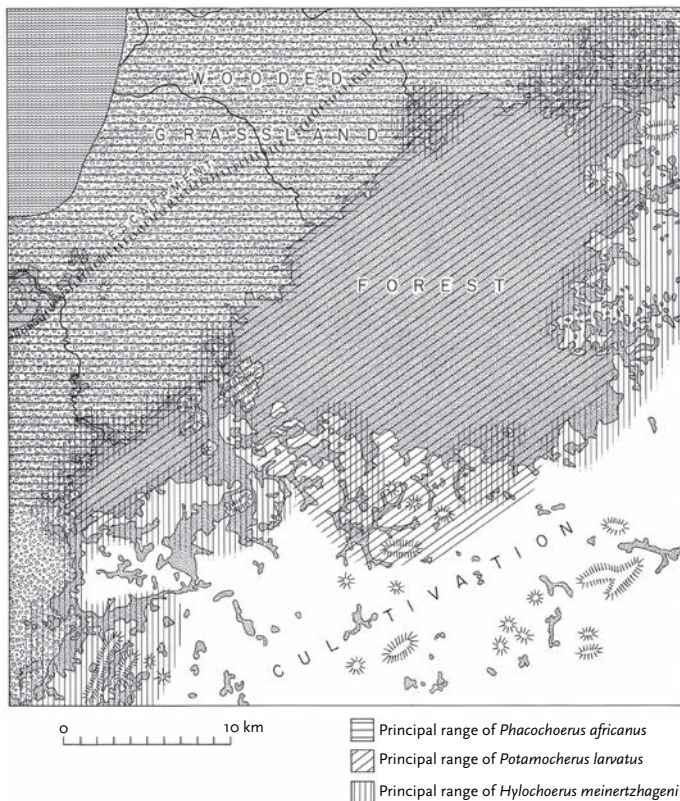

A major faunal turnover occurred toward the end of the Miocene (7–5.3 mya) in sub-Saharan Africa, reflecting the opening up of forested habitats and the spread of C4 grasses (Leakey *et al.* 1996, Cerling *et al.* 1997b). The listriodonts, kubanochoeres and sanitheres characteristic of the African early and middle Miocene were replaced by tetraconodonts in the late Miocene and these were in turn replaced by suines that arrived during the late Pliocene (3–1.8 mya). The contrast in size between the relatively small early and middle Miocene African suids and their larger late Miocene and Pliocene counterparts reflects the more open habitats available to the later forms.

The Suinae are first documented in Africa at about 3.4 mya. *Kolpochoerus*, *Potamochoerus* and *Metridiochoerus* represent the ancestral stocks of the extant forest hogs (*Hylochoerus*), bushpigs (*Potamochoerus*) and warthogs (*Phacochoerus*), respectively (Cooke 1978a, Harris & White 1979). *Potamochoerus* remained virtually unchanged during the ensuing 3-plus million years, but some of the *Kolpochoerus* and *Metridiochoerus* species underwent increase in size and in complexity of the cheekteeth. Later members of both the *Kolpochoerus* and

Metridiochoerus lineages achieved gigantic size but *Hylochoerus* was probably derived from the moderately sized *K. heseloni*, whereas *Phacochoerus* probably originated from the diminutive *M. modestus* (Harris & White 1979).

Today, the African suids live in wooded or thicket country, from rainforest and montane forest to savannas and semi-arid scrub, which provides requisite shelter. In some rare localities the ranges of all three genera overlap, but their ecological preferences and spatial partitioning are clear, with bushpigs preferring forest and thicket formations, warthogs in wooded savannas and the Forest Hog in forest/grassland mosaics. All species are capable of expanding their ecological range in the absence of the other species. They typically live in groups of one or more ♀♀ (sows) with young; adult ♂♂ (boars) are predominantly solitary. Females in most species make nests, to which they constantly return with their young; warthogs occupy burrows. Litters typically number 2–8 and single births are rare. The very large size achieved by some extinct Pliocene and Pleistocene African suids was probably a predator-selected adaptation for living in more open habitats.

John M. Harris

Tribe SUINI

Old World Pigs

Suini Gray, 1821. London Med. Repos. 15: 306.

ABOVE: Diagrams of upper third molar in (left) Forest Hog *Hylochoerus meinertzhageni* and (right) Bushpig *Potamochoerus larvatus*.

LEFT: Three suid skulls showing flexion of snout in relation to cranial capsule: a) Bushpig *Potamochoerus larvatus*; b) Common Warthog *Phacochoerus africanus* (down); c) Forest Hog *Hylochoerus meinertzhageni* (upward).

Africa is home to three extant suin genera. The Wild Boar *Sus scrofa* was at one time restricted to North Africa, but feral stock is now also known from western and southern parts of the continent. The Forest Hog *Hylochoerus meinertzhageni* is essentially limited to the equatorial forest belt, but the bushpigs (*Potamochoerus* spp.) are more widely distributed in the less arid parts of Africa. Bushpigs are water-dependent opportunistic feeders that will take advantage of any available food source; Warthogs, in contrast, feed exclusively on C3 plants and are less water-dependent (Harris & Cerling 2002). All three genera were originally bunodont browsers or omnivores, but derived Pleistocene species of the extinct African suin *Kolpochoerus* had high-crowned teeth and a grazing diet (Harris & Cerling 2002).

In common with some other pigs, the braincases of Suini are enclosed in bony capsules that are separate from the skull's outer casing. One benefit of this separation between the cranium, with its associated basicranial axis, and the skull's outer shell is that the latter can be damaged (and often is during violent male fights) without compromising brain function. Another attribute is very ready modification of the outer shape of pig skulls during evolution.

The Suini evidently originated in western Asia (Pickford 1993), from whence they migrated to eastern Asia, Europe and Africa. *Kolpochoerus deheinzeli*, known by teeth from the latest Miocene of Chad (Brunet & White 2001), is the oldest suin yet documented in the African record. The cranium of the Pliocene *K. afarensis* was rather similar to that of bushpigs but with downwardly drooping zygomatic arches and less prominent canine flanges (Cooke 1978b); in ♂♂ of later species, the zygomatic arches were pneumatized. Harris & White (1979) postulated that *Hylochoerus* was derived from *Kolpochoerus* during the early Pleistocene and that the scarcity of fossil *Hylochoerus* specimens is an artefact of their preferred habitat. Although a few teeth attributable to *Potamochoerus* have been recovered from late Pliocene localities in East Africa (Harris & White 1979), fossil bushpigs are similarly elusive and for the same reason. *Sus* appears to have been a post-Pleistocene immigrant to North Africa.

GENUS *Sus* Wild Boar

Sus Linnaeus, 1758. Syst. Nat., 10th edn, 1: 49.

The genus *Sus* includes ten extant species (Grubb 2005), of which only one, the Wild Boar *Sus scrofa*, occurs in North Africa. However, this species has been introduced elsewhere on the continent.

Of the extant African suins, the ecologically equivalent Wild Boar and Bushpig *Potamochoerus larvatus* are of similar size and share many characteristics, including small upper tusks, three pairs of upper incisors, and relatively unspecialized, low-crowned bunodont cheekteeth, but *Sus* has a full complement of premolars and its enamel is thinner. The skulls of both *Sus* and *Potamochoerus* are elongate and pointed (or wedge-shaped) with an almost straight profile from the tips of the nasals to the parietals. The braincase is gently domed behind the orbits with a narrow parietal constriction. The snout of *Sus* is long and narrow with parallel-sided nasals, whereas in *Potamochoerus* the nasals widen above the canine flanges and in ♂♂ there is an expanded rugose area on the nasals and the adjoining parts of the maxillae. *Sus* has only small maxillary flanges around the roots of the upper canines, even in ♂♂, whereas in *Potamochoerus* the canine flanges are strongly developed and rugose in their upper portions. The zygomatic arches of *Sus* are narrow and not expanded laterally whereas in *Potamochoerus* the maxillary root of the zygoma juts out sharply and may be quite inflated in ♂♂. *Sus* lacks the distinct small shelf on the back of the mandibular symphysis for

the attachment of the genioglossus and geniohyoideus muscles that are present in bushpigs.

The earliest (mid-Miocene) representatives of the genus *Sus* conceivably derive from Asian *Propotamochoerus* stock. By the end of the Miocene the genus was widespread throughout Eurasia. In Europe, *Sus* was the dominant suid genus from the Pliocene onwards; the small *S. arvensis* characterized the early Pliocene, but overlapped with the very large *S. strozzi* in the later Pliocene. The extant species *S. scrofa* appeared in the late early Pleistocene. In Asia, *Sus* competed with other suine genera during the Pliocene and later diversified into a number of different species whose extant representatives are collectively known as the warty pigs (Groves & Grubb 1993). Curiously, *Sus* was not part of the suine radiation that brought *Potamochoerus*, *Kolpochoerus* and *Metridiochoerus* to sub-Saharan Africa during the early Pliocene and the Wild Boar was a relatively late immigrant to the continent. Cooke & Wilkinson (1978) indicated that remains of *S. scrofa* were present at many later Pleistocene sites in North Africa and the species is also documented at the mid-Pleistocene localities of Ternifine (Pomel 1896) and Mansoura (Joleaud 1933) in Algeria. The genus was not found south of the Sahara until introduced there through human agency.

John M. Harris

Sus scrofa WILD BOAR (EURASIAN WILD PIG)

Fr. Sanglier; Ger. Wildschwein

Sus scrofa Linnaeus, 1758. Syst. Nat., 10th edn, 1: 49. 'Habitat in Europa australiore'; shown to be Germany, from where wild boar had been introduced to Sweden, Oeland (Thomas 1911: 140).

Taxonomy Wild Boar populations show considerable variation in body size, cranial morphology and coat colour. Groves (1981a) recognized 16 subspecies, which can be assembled into four regional

groups (Groves & Grubb 1993): the Western subspecies (*S. s. scrofa* and *S. s. meridionalis*, distributed in Europe; *S. s. algira*, in North Africa; *S. s. lybicus*, in south-west Asia, and extinct in the Nile Delta,

Wild Boar *Sus scrofa*.

Wild Boar *Sus scrofa*.

Sus scrofa

though the origin of this population is obscure; and *S. s. attila* and *S. s. nigripes* in Central Asia); the Indian subspecies (*S. s. davidi*, in the sub-Himalayan region; *S. s. cristatus*, in NC India, Myanmar and W Thailand; *S. s. affinis* and a new, undescribed subspecies, in S India and Sri Lanka); the Eastern subspecies (*S. s. sibiricus*, in Mongolia; *S. s. ussuricus*, in eastern Asia; *S. s. leucomystax* and *riukiuanus*, in Japan; *S. s. taivanus*, in Taiwan; *S. s. moupinensis*, in S China and Vietnam); and the Indonesian subspecies *S. s. vittatus*, which is distributed in the Malay Peninsula, Sumatra, Java, Bali). All extant North African Wild Boars belong to *S. s. algira*; *barbarus*, the name sometimes used for this subspecies, is a *nomen nudum*. In Tunisia, molecular data reveal a clear break between northern and southern populations, possibly due to an Algerian origin of the southern animals (Hajji & Zachos 2011).

Synonyms: Grubb (2005) lists numerous synonyms, but only *algira*, *barbarus* and *sahariensis* pertain to Africa. Three variations of chromosome number have been recorded in wild populations, with $2n = 36, 37$ and 38 , due to Robertsonian translocations (Bosma 1976, Mauget *et al.* 1977, Popescu *et al.* 1980, Jotterand-Bellomo & Baetting 1981, Mayr *et al.* 1984, McFee *et al.* 1986, Arroyo-Nombela *et al.* 1990). The chromosome number of Wild Boars in North Africa is $2n = 38$ (El Mastour *et al.* 1983), but this requires confirmation as the origin of the two animals analysed (from Tunis Zoo) is uncertain.

Description A grey, brownish pig of intermediate body size, with relatively short muzzle and no facial warts. The head profile is triangular. Ears rather large, not tufted. Snout elongated, the tip of which is flat and forms a cartilaginous rhinarium, which is used in digging. Limbs relatively long. Hair colouration agouti, in general greyish, blackish or brown; there may be whitish hairs on the face, cheeks and throat. Hairs are often dense, and the bristles on the dorsal line are long, sometimes forming a crest or a mane. Piglets longitudinally striped brownish-red during the first five to six months. Tail has tufts. Females are smaller and about 28% lighter than ♂♂ (El Mastour *et al.* 1983, Abáigar 1990). Females have four to six pairs of nipples.

The dental formula is $I^{3/3}, C^{1/1}, P^{4/4}, M^{3/3} = 44$. Large upper canines are present, the length of which depend on the age, with their alveoli directed outward, curved outwards, backwards and upwards.

Geographic Variation As noted under Taxonomy above, there is considerable geographical variation in colour and morphology, and many subspecies have been recognized, which Corbet (1978) states have never been shown to have discrete boundaries.

Similar Species The Wild Boar cannot be confused with any other suid species within its range in Africa.

Distribution The Wild Boar is widely distributed in the Palearctic region and shows the largest range among all the suiforms. On the African continent, the species occurs naturally only in North Africa, then extraliminally formerly in Europe (including the British Isles), through S Russia, the Middle East and South Asia to the Malay Peninsula and the Greater Sundas. They are also present on Japan and Taiwan. The Wild Boar was eradicated in the British Isles and also in southern Scandinavia and N Japan in the seventeenth century. Isolated populations still exist on Honshu, and on Sardinia and Corsica (the only Mediterranean islands to which they are native), but their range also has been significantly expanded through reintroductions and introductions. Local populations in western and central Europe have been intensively restocked with allothonous or hybrid animals for hunting purposes. The species has been introduced in the USA, Australia, New Zealand, the Lesser Sundas, West Indies, and numerous oceanic islands, including the Galapagos and Hawaii (Ellerman & Morrison-Scott 1951, Corbet 1978, Oliver *et al.* 1993, Grubb 2005).

On the African continent, domestic pigs were released into plantations in the Western Cape of South Africa in an attempt to control the Pine Tree Emperor Moth *Nudaurelia cytherea* (Thomas & Kolbe 1942), but their invasive potential has been minimal when

Lateral, palatal and dorsal views of skull of Wild Boar *Sus scrofa*.

compared with other parts of the world (Botha 1989); they also have been introduced to several other African countries (e.g. Gabon, Sudan, Burkina Faso; Vercammen *et al.* 1993).

Historical Distribution Formerly in North Africa (north of 26° N) from Morocco's lower Segua El Hamra (Morales Agacino 1950) through N Algeria, Tunisia and N Libya to the Nile R. in N Egypt (Osborn & Helmy 1980). The origin of Egyptian animals is questionable, as they probably represent indefinite crossings between wild and domesticated animals (Manlius & Gautier 1999). Animals from Sudan are also probably of domesticated origin (Ansell 1972, Manlius & Gautier 1999), as are animals from the offshore islands of Mafia and Pemba (Haltenorth & Diller 1980). Fossil remains of the Wild Boar are common in Pleistocene and Holocene layers in north-west Africa, and the animal is also depicted on Roman mosaics in ancient Libya (Kowalski & Rzebik-Kowalska 1991).

Current Distribution In North Africa, confined to Maghreb (north of 27° N) from Morocco (south-western limit south of the lower Draa R.) to Tunisia. Probably no longer occurs in Libya (where the last observation dates from 1883), and extinct in Egypt since about 1902 (Hufnagl 1972, Osborn & Helmy 1980).

Habitat Inhabits a variety of well-vegetated environments, from forests to dense steppes, including marshes and riparian vegetation, in areas with over 150 mm annual rainfall. Wild Boars are able to inhabit very steep slopes, and usually are more abundant on northern rainy slopes and in gullies (Cuzin 2003). Under drier climate (between 50 and 150 mm annual rainfall), in northern Sahara, confined to humid environments (oases, marshes and riparian habitats, especially in *Tamarix* thickets). In Morocco, they occur from sea level up to 2750 m in the High Atlas, though more common between 1500 and 2250 m

(Cuzin 2003). In Algeria, they range up to 2300 m in Djurdjura (K. De Smet pers. comm.). Usually needs water for drinking, but may live without any water in summer, for example, in Djebel Guettar (Algerian hauts plateaux) (Heim de Balsac 1936).

Abundance In Morocco, Wild Boars seem to attain their highest densities in dense forest, as they do in south-eastern Andalusia, Spain (Abáigar *et al.* 1994). In Algeria and Tunisia, numbers are rising everywhere and the species is recolonizing parts of its former range, as in the Bou Hedma (K. De Smet pers. comm.).

Adaptations Mainly crepuscular and nocturnal, but active also during the day in undisturbed areas (Benhamza 1995). In C Morocco, there are two peaks of activity at night, between 21:00 and 01:00h and between 03:00 and 07:00h (El Mastour *et al.* 1983). Animals tend to stay in the densest available vegetation during the day. Adults wallow in mud, where available.

Foraging and Food Much of what is known about diet in Africa originates from studies in C and N Morocco (El Mastour *et al.* 1983) and N Algeria (Klaa 1992). Wild Boars are mainly herbivorous, the major part of the diet consisting of aerial and subterranean parts of plants. Leaves, stalks and fruits (*Quercus* spp., *Chamaerops humilis*, *Ceratonia siliqua*, *Rhus pentaphylla*) are consumed. In SE Andalusia, during autumn, acorns of oaks *Quercus ilex* may constitute the main part of the diet (Abáigar 1993). Wild Boars intensively dig for roots and bulbs, especially those of *Arisarum vulgare*, when the soil is not too hard, mainly after the rains and under forest cover with well-developed or humid soils; this activity is very limited in dry areas, where soil is usually too hard (Cuzin 2003). A minor, but common, part of the diet consists of insects, annelids, myriapods, snails and other invertebrates, and, occasionally, some meat, eggs, small mammals (Panouse 1957) and larger animals, probably as carrion. Strong canines allow them to open carcasses very efficiently, thereby allowing other small scavengers to feed (K. De Smet pers. comm.). In SE Andalusia, young animals consume more animal matter (Abáigar 1993).

There is some evidence of seasonal variation in diet, with leaves and stalks mainly consumed after rains, usually in winter and spring; fruits are consumed from autumn to spring, and digging activity is more frequent when the soil is not too hard. In Algeria, consumption of animal food seems more frequent in autumn. In the driest habitats, in the absence of rain, animals may move to more productive habitats, e.g. oases (F. Cuzin pers. obs.), where they eat a lot of dates (K. De Smet pers. comm.). After periods of high rainfall in the N Moroccan Sahara, animals moved up to 110 km from their native area, returning there when the habitat dried out (F. Cuzin pers. obs.). Wild Boars are attracted to agricultural fields, especially cereals, maize, wheat and barley.

Social and Reproductive Behaviour Wild Boars are gregarious, occurring in groups of up to 17 animals (Benhamza 1995). In Europe, groups of generally related ♀♀ with piglets, and subadult ♀♀ are the most common social unit, while ♂♂ stay isolated or in small groups, joining female groups only during the rutting season; territorial behaviour is evident only for resting places (Gerard *et al.* 1991).

There are no details of home-range size in North Africa. In S France, home-ranges are very variable according to the season:

Maillard & Fournier (1994) recorded an average of 263 ha for groups and 1063 ha for lone ♂♂ during summer, and 497–15,440 ha for ♀♀ and 1292–3698 ha for ♂♂ during autumn. Dispersal is more common among ♂♂ than ♀♀.

Wild Boars have a wide range of vocalizations, from rhythmic grunting of ♀♀ when leading groups to teeth-chattering when angry.

Reproduction and Population Structure Mating usually occurs from Oct until Jul (thereby avoiding the driest season), with parturition from Feb until Oct, with a peak in Mar (El Mastour *et al.* 1983). Gestation is 112–126 days in Europe (Gerard *et al.* 1991). Mean litter-size is 5.7 (range 2–11; $n = 13$), according to foetal counts, and 5.1 (range 3–8) based on direct observations (El Mastour *et al.* 1983). Time to weaning is not recorded for North Africa, but in Europe, ♀♀ stay alone from the end of gestation until 1–5 weeks after birth (Gerard *et al.* 1991). Young are mature at 7–12 months of age. Longevity and population structure is unknown in North Africa.

Predators, Parasites and Diseases Leopards *Panthera pardus* have been observed feeding on Wild Boar (P. C. Beaubrun & J. Godart pers. comm.), although this species is on the verge of extinction in North Africa (Cuzin 1996). There are also reports of Golden Jackals *Canis aureus* preying on young (Khidias 1986). There is no information available on their susceptibility to disease or parasites in North Africa.

Conservation IUCN Category: Least Concern. CITES: Not listed.

The primary threat to the Wild Boar in North Africa is forest loss and habitat degradation, coupled by a drying of humid habitats, especially on the northern fringes of the Sahara (Cuzin 2003). Nonetheless, Wild Boars are expanding their range in some parts (Cuzin 1996), and in Tunisia and Algeria they are gradually expanding southwards, especially in the wake of the Islamic uproar in the Tell Atlas, and a ban on hunting (Kowalski & Rezebik-Kowalska 1991, K. De Smet pers. comm.). Though considered as impure by Islamic

belief, Wild Boars are a pest in agricultural fields and are sometimes hunted by local people (Monteil 1951, F. Cuzin pers. obs.).

Measurements

GENUS *Potamochoerus*

Bushpig, Red River Hog

Potamochoerus Gray, 1854. Proc. Zool. Soc. Lond. 1852: 129 [1854].

This genus is represented by two very distinct species (Grubb 1993b): the monotypic Red River Hog *P. porcus*, characteristic of the rainforest belt but extending north of it into savanna country; and the geographically varying Bushpig *P. larvatus*, of heavy cover in the East and southern African savanna zone. The Bushpig was introduced in precolonial times to Madagascar (also the type locality for the species), where it flourishes; the reasons for its introduction seem obscure, but presumably relate to meat supply.

Potamochoerus is the most plesiomorphic of the three endemic Afrotropical genera of Suidae, and is presumed, on morphological grounds, to be the sister genus of *Sus*, with which it shares the following character states: the rostrum is extremely elongated; there is a deep preorbital fossa; and the temporal ridges are strongly

developed. The canines of the ♂, which are comparatively small, flare sideways and curve upward; those of the ♀ are much smaller, but likewise protrude sideways. The root of the maxillary canine sits in a large bony flange, the canine apophysis, which protrudes from the anterior maxilla lateral to the rostral end of the preorbital fossa. Also in common with *Sus* is the presence of three upper incisors. The premolars, contrary to the two other endemic Afrotropical genera, are not only well developed, but are enlarged and somewhat molarized. The adult dental formula is: $I^{3/3}, C^{1/1}, P^{3-4/3-4}, M^{3/3} = 40-44$.

In contrast to *Sus*, however, pigs of this genus are characterized by several important differences: the braincase bulges outward below the temporal ridges; the occiput is lower; the auditory canal, instead of ascending at 45 degrees or more, is relatively horizontal; and the

nasals are dorsally flattened, and laterally expanded, so that they overhang the lateral walls of the rostrum. The canine apophysis of the ♂ is greatly enlarged and roughened, and rises up toward the shelf-like lateral nasal edge. The anterior premolar is always absent in the mandible, commonly so in the maxilla (see dental formula above). The other premolars are strongly molarized, with flattened, cuspidate occlusal surfaces (in *Sus*, they have narrow blades). The mandibular ascending ramus slopes more posteriorly than in *Sus*, and the condyle is relatively lower. Ewer (1958) described the functional anatomy of

the facial musculature, relating it to the mobility of the snout, especially its terminal disc.

Externally, this genus of mainly nocturnal omnivorous pigs is characterized by the long, pointed ears; and, among the Afrotropical genera, by the longitudinal ridges along the top of the snout and forehead; by the retention of a long, bristly pelage; and by the lack of prominent facial warts, but the presence of a flat wart on either side of the snout supported by the enlarged canine apophyses.

Colin Groves

Potamochoerus larvatus BUSHPIG

Fr. Potamochère; Ger. Buschschwein

Potamochoerus larvatus (F. Cuvier, 1822). Mem. Mus. Hist. Nat. Paris 8: 447. Madagascar.

Taxonomy The Bushpig was originally considered conspecific with the Red River Hog *Potamochoerus porcus*, which is now regarded as a separate allopatric species of West and central Africa (Grubb 1993b, 2005; and see De Beaux 1924). Grubb (1993b) noted that too many subspecies have been recognized in the past, and commented that the primary systematic division within the species is between the white-faced animals of East Africa and populations in southern Africa. He tentatively recognized three subspecies on the African mainland (*Potamochoerus larvatus hassama*, *P. l. somaliensis* and *P. l. koiropotamus*) and an additional two on Madagascar and Comoros Is. (*P. l. larvatus* and *P. l. hova*). However, Vercammen *et al.* (1993) proposed that insufficient evidence exists for the recognition of *P. l. somaliensis* as a distinct subspecies (indeed, Grubb 1993b was not convinced of the validity of *somaliensis* either), and recognized only two from the continent: the White-faced Bushpig *P. l. hassama* (including *P. l. somaliensis*; East Africa) and the Southern Bushpig *P. l. koiropotamus* (from Angola and southern Africa). The Madagascan and Comoron subspecies of the Bushpig were almost certainly introduced during historic times. Synonyms: *africanus*, *arrhenii*, *choeropotamus*, *congius*, *cottoni*, *daemonis*, *edwardsi*, *hassama*, *hova*, *intermedius*, *johnstoni*, *keniae*, *koiropotamus*, *madagascariensis*, *mashona*, *nyasae*, *somaliensis*. Chromosome number: not known, but presumably as for *P. porcus*. Hybrids with introduced feral pigs *Sus scrofa* have been recorded (Milstein 1971, Smithers 1983).

Description Medium-sized, thickset suid. The head is characterized by an elongated muzzle, with naked disc-like snout, cheek beards and terminal ear tassels. The morphology of the head differs between the sexes and the slightly heavier male body mass is related to these differences. Males develop three pairs of wart-like facial structures: over the canine root flanges on the snout (preorbital); on the malar eminences (infraorbital); and on the jaw angles (gonial). Ears pointed with tufts of long hair at tips. Pelage bristly, extending from the head over the whole body, with a striking dorsal crest extending from the head to the base of the tail; hairs long (60 mm), but relatively sparse. Undercoat absent. General colour variable within and between subspecies and individuals, and changes with age. Neonatal pelage of pale, yellowish-buff stripes on a brown ground colour is replaced by a rufous-brown at about three months of age, gradually changing to the colouration of maturity. Adult

Bushpig *Potamochoerus larvatus*.

body colour is predominantly black to dark grey, but, particularly in north-eastern parts of the range, may be light red to brown. Males often have a distinct white facial mask. Tail with sagittally aligned (feathered) black terminal hairs. Males have tusk, orbital (Harderian), digital and preputial glands; orbital and digital glands are found in ♀♀. Females have three pairs of nipples.

The highest point of the skull lies near the back and then slopes forward to the nostrils. Rostrum narrow and elongated, hollowed out on either side to accommodate the powerful muscles and tendons that open and close the rhinarium during rooting and digging. Mandible long and massive, its actuation relying on the powerful masseters provided with firm attachment between the thick zygomatic arches and the angle of the lower jaw. Supraoccipital ridges pronounced. The back of the skull arches high from the occipital condyles and provides a firm base for the attachment of the neck muscles, which actuate the movement of the heavy head. Adult dentition is developed at about two years, M³ being the last to erupt. The incisors are heavily built and persist throughout the life of the individual. The upper canines project outside the mouth cavity but are never as long as in warthogs *Phacochoerus* spp.; the lower canines are sharp-pointed and sharp-edged, lying at an angle sloping outwards from the mandible, which

Lateral, palatal and dorsal views of skull of Bushpig *Potamochoerus larvatus*.

makes them formidable weapons. The molars are brachyodont and bunodont, and in old individuals still retain some ridging indicating a chopping action rather than grinding during mastication (Seydack 1983, Skinner & Chimimba 2005).

Geographic Variation

P. l. hassama (including *P. l. somaliensis*) (White-faced Bushpig): East Africa, including Ethiopia, Eritrea, S Sudan (both west and east of the Nile R.), E DR Congo, Rwanda, Burundi, Uganda, Kenya and NTanzania. Characterized by the white colour of the head, usually black body in adult ♂♂ and smaller average size, as indicated by skull length (32.7–35.3 cm in ♀♀ and 34.1–37.7 cm in ♂♂; Grubb 1993b).

P. l. koiropotamus (Southern Bushpig). SE DR Congo, S Tanzania, Malawi, Mozambique, Zambia, W and C Angola, Zimbabwe, Botswana, South Africa and Swaziland. Largest member of the genus (skull length 36.7–41.5 cm in ♂♂ and 34.5–39.5 cm in ♀♀), typically never with contrasting black-and-white colour pattern of *P. l. hassama*, but ♂♂ from an isolated population in the Western Cape and Eastern Cape also generally have white faces contrasting with darker bodies. It is also possible that darker-bodied Bushpig ♂♂ have whitish facial patterns, whilst lighter-bodied ones have darker facial markings for contrast.

Similar Species

Potamochoerus porcus. Allopatric, though ranges are contiguous in places. Predominant coat colour bright russet-orange with a white dorsal line; pelage over much of body short and dense; terminal ear tassels particularly elongated; forehead black or dark brown, with prominent white 'spectacles' around eyes.

Hylochoerus meinertzhageni. Sympatric in some parts of eastern Africa. Larger, more heavily built suid, with long black hair, and a dorsal crest of thick, erectile hair; ♂ has enormous bare cheeks and a broad, flat muzzle.

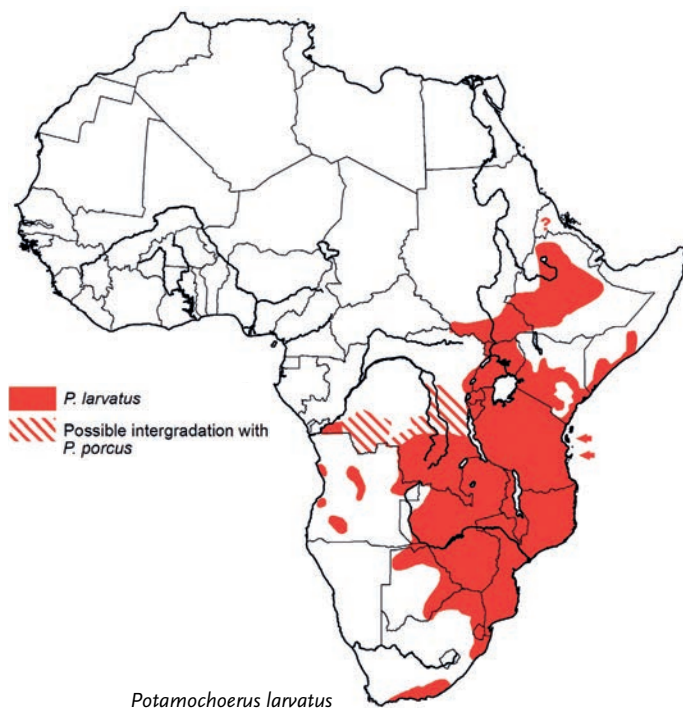

Bushpig *Potamochoerus larvatus* juvenile skeleton.

Bushpig *Potamochoerus larvatus* myology of juvenile.

Bushpig *Potamochoerus larvatus* juvenile.

Distribution Endemic to Africa, extending from S Sudan, Ethiopia and possibly Eritrea in the north-east of the continent, southwards through East Africa and E and S DR Congo to Zambia, Malawi and Mozambique. There are isolated populations in W and C Angola. In DR Congo, the vicinity of the upper reaches of northward-flowing tributaries of the Congo R. are occupied by this species, whereas the continuous lowland forest that surrounds more northerly reaches of the same rivers is inhabited by Red River Hogs. In southern Africa, they are absent from Namibia, though they may occur in the Caprivi Strip. In Botswana they occur only in the northern and north-eastern parts, while in Zimbabwe they occur nearly throughout. In South Africa they are found in the northern and eastern parts of the country (and neighbouring Swaziland) to S KwaZulu–Natal. There is a break in their distribution between S KwaZulu–Natal and an isolated population in the Eastern Cape and Western Cape Provinces (which is also the origin of the holotype). Recorded from Zanzibar (Pakenham 1984) and Mafia I. (Kingdon 1979, Kock & Stanley 2009), and introduced on Madagascar and the Comoro Is. (Mayotte) off the east coast of Africa (Vercammen *et al.* 1993).

Habitat Bushpigs are associated with relatively dense vegetation types with available food, cover and water, occurring in forests and riverine or xeric scrub forests and thicket formations. In East Africa they commonly are found in high-lying areas, such as the Ethiopian Highlands to elevations of 3000 m, and perhaps 3400 m (they are common in the Haremma Forest; Yalden *et al.* 1996), the highlands of the Albertine Rift (where Red River Hogs have never been recorded), and on Mt Kilimanjaro (to 4000 m; Vercammen *et al.* 1993). They also maintain their occurrence in areas now given over to subsistence farming or to agricultural crops such as sugarcane, maize, peanuts and beans, and have long been a serious problem in such areas.

Abundance Mentis (1970) reported 0.22 individuals/km² in Hluhluwe–iMfolozi G. R., KwaZulu–Natal, South Africa. Population density estimates during a study in southern Cape forests, South Africa, range between 0.3 and 0.5/km² (Seydack 1990, 1991).

Adaptations Bushpigs obtain the largest proportion of their food from the litter layer through superficial rooting. The compact body and thick short neck allow for the necessary digging forces to be applied. The build of the skull with its long snout, forwardly sloping lower incisors, short canines and bony support for the rhinarium (discussed above) are all adaptations for searching for food by rooting and digging, while their bunodont dentition and monogastric digestive system make the Bushpig well suited to an omnivorous diet. Olfaction plays a prominent role in locating food items.

The thermoneutral zone is between 13 and 30°C for juveniles and between 8 and 25°C for adults (Seydack 1990). Accordingly, Bushpigs avoid temperature extremes, being active preferentially between 18:00 and 22:00h in both summer and winter. In summer, Bushpigs rested mainly between 10:00 and 18:00h and in winter between 10:00 and 14:00h and 2:00 and 6:00h (Seydack 1990). Thus, although primarily nocturnal, more diurnal activity may occur during winter. Behavioural thermoregulation includes wallowing, lying in extended posture and exposure to air movement at high temperatures and resting after midnight in winter, sheltering, huddling and nest-building during cold and wet spells.

Foraging and Food Bushpigs are omnivorous generalists, feeding opportunistically, but primarily on subterranean and above-ground herbaceous plant material. The diet of Bushpigs in the Knysna Forest of the Western Cape and the valley bushveld regions of the Eastern Cape (South Africa) comprised 40% subterranean plant structures (of which 54.3% consisted of rhizomes, 38.9% tubers, 5.7% roots and 1.1% corms), 30% above-ground herbage (of which 46% consisted of monocotyledons, 38.7% fern fronds and 12.3% dicotyledons), 13% fruit, 9% animal matter and 8% fungi (Seydack 1990). The most important dietary items in the Cape were underground fungal bodies of *Rhizopogon*, bracken (*Pteridium aquilinum*) rhizomes and *Blechnum punctulatum* fronds. In the Eastern Cape, tubers of Vitaceae (*Rhoicissus* and *Cyphostemma*), vertebrate animal matter and foliage of *Aloe ciliaris* predominated (Seydack 1990).

In Matobo N. P. in Zimbabwe, Jones (1984) recorded 29 different food items, including invertebrates (earthworms). During the wet season, 37% of identifiable food remains in faeces were fruit, 26% finely digested food and 19% herbaceous plant roots; during the cool dry season 49% was finely digested food and 41% fruit; and in the hot dry season 83% were woody plant roots. Both wild and cultivated fruits are eaten and Bushpigs may be particularly troublesome in maize fields, sugarcane and other planted crops (Skinner *et al.* 1976, Melton *et al.* 1989). Carrion is taken opportunistically (Skinner *et al.* 1976 and references therein, Jones 1984).

Dietary items are procured from a feeding stratum of ± 0.5 m above and below ground surface through superficial rooting, deep rooting and grazing. During superficial rooting, which is the most commonly employed foraging technique, subterranean food items are exposed by lifting the snout forward and upward through the earth or litter layer. In moist or loose earth, the snout may be worked well into the soil in pursuit of deeper subterranean food items.

Bushpig *Potamochoerus larvatus*.

Suitable dietary items for an omnivore are typically widely dispersed in space and time. This requires much searching and Bushpigs move continuously while foraging, stopping only when a clump of food is discovered. When foraging in a group they tend to be spaced out in a variably extended formation. Bushpigs are predominantly nocturnal (Breytenbach & Skinner 1982, Seydack 1990). The main phase of intensive foraging generally occurs from before dusk to midnight, with a secondary activity phase in the morning. Animals are active for an average of 13.7 hours per day (Seydack 1990). This represents a comparatively extended activity period and is presumably related to the search time required where food is dispersed. They visit habitat with poor vegetation cover only during the hours of darkness.

Social and Reproductive Behaviour Bushpig sociality is characterized by the family group, usually consisting of a boar and a sow with one or two generations of offspring. There is typically only one adult sow per family group (sounder). Populations may be subdivided into four socio-spatial classes: territorial male–female pairs with or without progeny; solitary individuals, in the case of ♂♂ occupying non-exclusive home-ranges; and dispersing individuals that are mainly yearlings or subadults and nomadic adults. The average group size for the study populations in the Knysna Forest was 2.4 individuals, ranging between one and ten (Seydack 1990).

Resource territoriality is maintained by spatially related high levels of aggression, notably between ♀♀, and patrolling and marking behaviour. The area of the average home-range or territory

in the Knysna Forest was 7.2 km² (3.8–10.1 km²; n = 8) (Seydack 1990). Home-ranges are traversed every one to four days, with an average daily ranging distance of about 3 km (0.48–5.84 km).

The monogamous mating system is characterized by extended male–female pair bonds, lasting beyond mating and rearing periods, and by breeding of only the alpha-female within each territory. Breeding deferment of sexually mature, pre-dispersal daughter sows may be associated with alloparental care, consisting of grooming and remaining in close proximity to neonates. During rearing of the young, which remain with the parents long past weaning, substantial male parental care is involved. The offspring usually disperse from the family home-range when between 1.5 and 2.0 years old.

Farrowing may take place in shallow ground hollows. During cold or wet conditions, farrowing nests may be prepared during parturition. Nests then consist of a shallow depression lined with grass upon which additional twig material and shrubbery is piled to form an insulating heap. Neonates follow the mother away from the birth nest or hollow within the first one to three days, initially for short distances only. Within the first three weeks postpartum the daily ranging of juveniles hardly exceeds 200 m. When compared with the average daily ranging distance, it is apparent that during these initial weeks the ranging of adults is constrained. One or both parents remain at the resting sites and close to the neonates, lying in body contact to protect the young against both cold and predators. Paternal care involves guarding of, and concern for the young, especially during the temporary absence of the mother on foraging bouts. Maternal behaviour conforms to the general passive suid pattern; in addition to suckling the young, there is some limited vocal communication, naso-nasal contact and defensive responses to neonate distress calls (Seydack 1990).

Sounds made by the Bushpig include grunts, squeals, snarls and snorts as in other suids (Frädrich 1974). Primarily the dominant boar in a sounder may give alarm by uttering a long, drawn-out, resonant grunt. When foraging, individuals in sounders emit monosyllabic soft grunts, presumably to maintain contact.

Male tusk pouch glands and digital glands in both sexes apparently play an important role in olfactory communication (Jones 1978). Marking primarily involves tusk gland marking by the ♂ and ground scratch marking by both sexes. Male Bushpigs mark objects by wiping them with the opening of the pouch gland, usually up and down stems of small trees. Both sexes scratch the ground forcefully with the front feet, leaving clearly visible slashes. It is the dominant boar in the group that marks with his tusk gland, presumably conveying information about social status, whereas ground scratch marking appears to convey information regarding territorial tenure.

Agonistic interactions include threat gestures, snout thrusting, pushing aside, squabbling, snap biting and chasing off. Display contests are apparently confined to ♂♂ and contribute to mutual assessment of dominance ranking. Actual fighting, as described by Skinner *et al.* (1976), is accordingly rare in male Bushpigs. In contrast, territorial ♀♀ are very aggressive in expelling intruders from the territory. When two adult sows fight they rapidly thrust and push with their snouts, striking blows sideways or slashing whenever the opportunity arises ('nose fencing'). Forehead contact forms a crucial part of the contest and the snouts are held in the form of crossed swords against each other. The contestants push-butt each other with vigorous forward movements of the head, continually striving

to regain close head contact. They may sustain severe wounds and wound sepsis is a significant cause of female mortality.

Latrines consist of scattered accumulations of faeces that appear to be used intermittently over long periods of time. Faeces accumulations are sited predominantly where the ground surface is clear of vegetation, such as bare stretches of paths and roads or in canopy openings. They tend to be visually conspicuous, indicating a possible role in communication.

Reproduction and Population Structure Males reach sexual maturity between 16 and 20 months of age, while ♀♀ may first conceive at 17–22 months. Depending on social position and nutritional status, successful breeding usually occurs much later. Only pair-bonded territorial sows rear young successfully. In southern Africa, the farrowing season lasts from spring to early autumn, with a pronounced spring peak (Sowls & Phelps 1968, Seydack 1990). The most favourable nutritional conditions for the lactating sow apparently occur during this period due to the abundance of new plant growth. Mean litter-size in the wild is 2.1 ($n = 32$; Seydack 1990), but often three to four piglets are born, the maximum recorded being eight (Phillips 1926, Milstein 1971). Gestation lasts 17 weeks, and neonates weigh between 600 and 1000 g (Sowls & Phelps 1968, Seydack 1990). Lactation lasts up to 5.5 months (Seydack 1990).

Within all age classes, mortality is often due to starvation. In the Knysna Forests, significant mortality factors are inclement weather and predation for immature Bushpigs, and intra-specific strife for adults, especially in ♀♀. Mortality estimates for one- and two-year-old Bushpigs varied between 40 and 45% and were similar in both age classes. Adult mortality rates varied between 19 and 27% per annum. Sex ratio is usually 1 : 1. The oldest free-ranging Bushpig was estimated to be 18 years old, but only very few individuals reach this age (Seydack 1990).

In a study involving both Western and Eastern Cape Bushpig populations, differences in life history traits were revealed. Generation length and life expectancy at birth were 6.6 and 2.8 years in the Western Cape (nutrient-poor environment) and 5.4 and 1.8 years in the Eastern Cape (nutrient-rich), respectively. Breeding ♀♀ in the Western Cape were fatter, while Eastern Cape ♀♀ were smaller and leaner but exhibited higher fecundity. These regional differences were interpreted as resulting from a higher dietary nutrient to carbon ratio and associated higher population turnover in the Eastern Cape in comparison with Western Cape populations (Seydack 1990, Seydack & Bigalke 1992).

Predators, Parasites and Diseases Verified cases of Leopard *Panthera pardus* predation on subadult Bushpigs are recorded. Bushpigs were also commonly hunted by Robust Chimpanzees *Pan troglodytes* in Gombe N. P., Tanzania (Wrangham & Bergmann Riss 1990). Bushpig mandibles belonging to individuals 2–3 months of age have been

collected below Crowned Eagle *Stephanoaetus coronatus* nests (Seydack 1990). Bushpigs in NE KwaZulu–Natal have been recorded infested with eight ixodid tick species, of which *Rhipicephalus maculatus* was the most abundant, and one louse species *Haematopinus latus* (Horak *et al.* 1991a). Little is known about diseases in Bushpigs. Whether *Potamochoerus* spp. act as vectors of tick-borne diseases, such as trichinosis, African swine fever and trypanosomes, has yet to be verified (Vercammen *et al.* 1993).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Bushpigs still occur widely in suitable habitat, albeit at naturally low population densities, and are present in several well-managed protected areas across their range. There is little indication that the distribution of the species has been, or is at present, substantially altered by human activities. They may be subject to localized declines and range contractions in some areas due to large-scale habitat destruction or as a result of hunting for crop protection and local consumption (Vercammen *et al.* 1993). In southern Africa, they are also sporadically subject to official population control measures when they feed on crops. However, their preferred habitat, nocturnal habits and relatively high reproductive potential are such that it has proved generally difficult to eliminate Bushpigs from larger tracts of relatively densely vegetated habitat.

Measurements

Potamochoerus larvatus

HB (♂♂): 1256 (1100–1540) mm, $n = 80$

HB (♀♀): 1207 (1090–1410) mm, $n = 74$

T (♂♂): 402 (335–432) mm, $n = 6^*$

T (♀♀): 361 (305–432) mm, $n = 4^*$

HF c.u. (♂♂): 247 (225–290) mm, $n = 59$

HF c.u. (♀♀): 241 (217–270) mm, $n = 53$

E (♂♂): 175 (151–203) mm, $n = 6^*$

E (♀♀): 178 (161–190) mm, $n = 4^*$

WT (♂♂): 72.3 (55.0–93.0) kg, $n = 84$

WT (♀♀): 68.9 (54.0–85.0) kg, $n = 104$

Western and Eastern Cape, South Africa (Seydack 1983); *Zimbabwe, Smithers & Wilson 1979)

Mean body weights of 52 ♂♂ and 61 ♀♀ from E Zambia are slightly heavier at 77.5 kg and 72.0 kg, respectively; the upper weight range recorded for a ♀ was 96.0 kg (Wilson 1968)

Record tusk length is 30.17 cm for an animal from the Save R., Mozambique (Rowland Ward)

Potamochoerus porcus RED RIVER HOG

Fr. Potamochère; Ger. Pinselohrschwein (Flusschschwein)

Potamochoerus porcus (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 50. 'Habitat in Africa' (West Africa); based on animals exported to Brazil (Simoons 1953).

Red River Hog *Potamochoerus porcus*.

Taxonomy The most recent review of the taxonomy of the Afrotropical suids by Grubb (1993b) concluded that the Red River Hog and Bushpig *P. larvatus* should be treated as two separate species based on their clearly distinct morphology, at least until further field studies take place to further investigate possible intergradation or hybridization (and see Lönnberg 1910, De Beaux 1924, Allen 1939). As geographical variation cannot be differentiated from individual variation, no subspecies are recognized (Grubb 1993b). Synonyms: *albifrons*, *albinuchalis*, *mawambicus*, *penicillatus*, *pictus*, *ubangensis*. Chromosome number: $2n = 34$ (Melander & Hansen-Melander 1980). The chromosome complement consists of 12 pairs of (sub)metacentric autosomes and 4 pairs of acrocentric autosomes (Musilova *et al.* 2010). In Wonga-Wongue Presidential Hunting Reserve in Gabon, these animals are reported to have interbred with introduced Wild Boars *Sus scrofa* and to have produced wild offspring (East 1990).

Description Smallest of the Afrotropical suids (Grubb 1993b), characterized by bright, russet-orange dorsal colouration, a narrow, pure white dorsal line starting behind the head, a striking facial mask and narrow, pointed, tufted ears. In boars there is an exostosis on each side of the snout extending laterally toward a hypertrophied apophysis on the canine sheath – each supports a single large external cutaneous wart. No infraorbital warts. Facial mask black with a whitish muzzle, white 'spectacles' around the eyes and white cheek whiskers. Ears black with a whitish upper rim and elongated tip, carrying a tuft of long white hairs. Hair on forehead and body relatively short and dense, flanks and belly carry some longer bristles.

Ventral pelage light orange with long white and orange bristles. Pelage of young piglets brown with beige-yellow longitudinal stripes and some spots. Legs blackish in colour. Sparse tuft of hair at distal end of tail. It is likely that Red River Hogs have the same scent glands as Bushpigs (Seydack 1990): maxillary tusk glands and preputial glands in ♂♂, milky secretions from the Hardarian glands located in the eye sockets, and digital glands in both sexes. De Boer (1980) also describes a chin gland. Females have three pairs of nipples. Males are larger than ♀♀. Skull similar in build to the Bushpig, with upper canines projecting outside the mouth cavity.

Geographic Variation Vercammen *et al.* (1993) note that geographical variation is slight, though there is an east (largest) to west (smallest) cline in body size in specimens from eastern DR Congo and Cameroon, respectively. Grubb (1993b) was unable to differentiate any geographical variation from individual variation.

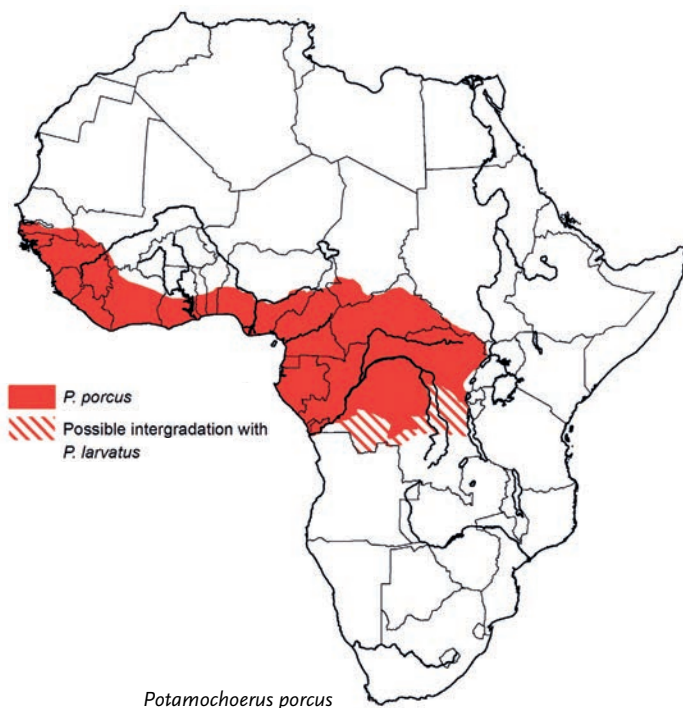

Lateral view of skull of Red River Hog *Potamochoerus porcus*.

Similar Species

Potamochoerus larvatus. As far as is known, the two species are allopatric, although their ranges are contiguous in some places (Grubb 1993b). Larger; pelage dominated by longer, coarse bristles, rather than thinner, shorter hair; much more variable and darker shaded body colouration (reddish-brown, grey and black) and more variable facial pattern (head never masked); ear tufts not so long.

Phacochoerus africanus. Sympatric over the south-west and south-central area of its range (Sahel until S Chad and possibly S Sudan in the east). Occurs on treeless open plains and lightly wooded savannas, but avoids densely wooded vegetation. Grey-brown skin, sparsely haired except for distinct black, brown or reddish mane of long thick hairs on neck and shoulders. Especially young animals often have a fringe of white hairs on cheeks. Ascending process of the mandible elongated; maxilla deepened, zygomatic arch much deepened and orbits displaced posterodorsally so that they rise above the shortened braincase. Tusks very long and curved. Prominent genal and rostral warts.

Distribution Endemic to Africa. Widely, but now patchily, distributed through the West and central African rainforest belt, from Senegal in the west, throughout the Guinea–Congo forest to at least west of the Albertine Rift. Further east and south-east replaced by the Bushpig, although the precise borders between the ranges of the two species remain unclear; for example, along the lower Congo R., below Kinshasa in DR Congo, the two species are separated only by this river – the smaller *P. porcus* occurring on the right bank and the large *P. l. koiripotamus* on the left (Angolan) side (Lönnberg 1910, Schouteden 1947, Grubb 1993b, Vercammen *et al.* 1993). Ghiglieri *et al.* (1982) observed pigs that they considered as intermediates between *P. l. hassama* and *P. porcus*, but Grubb (1993b), while noting that it was possible that the latter species may have made a narrow penetration of Uganda and hybridized with *P. larvatus* in the Kibale Forest, found there was insufficient evidence to support this. There are no confirmed records

from Sudan or Chad, though Red River Hogs may occur in extreme SW Sudan. There are also as yet no reliable records from Gambia, which is just outside their natural range (Grubb *et al.* 1998). Grubb (1993b) mentions a record from Bioko I. based on teeth picked up in the field (now in the Tervuren Museum), but notes this has yet to be evaluated.

Habitat Typically associated with rainforest and gallery forest, but also found in dry forest, savanna woodland and cultivated areas, although usually in close proximity to the rainforest and in regions with limited seasonality in terms of availability of water, food and cover (Odoro 1989, Vercammen *et al.* 1993). Also frequents hydromorphic forest clearings (Magliocca 2000) and mountains with steep slopes (Malbrant & Maclatchy 1949). Like the Bushpig, Red River Hogs are highly adaptable and may even benefit by the opening up of former forested areas by the creation of secondary habitats, the provision of cultivated foods and reductions in the numbers of their natural predators.

Abundance Densities (individuals/km²) reported for Red River Hogs vary greatly and include: 3.1 (Fa & Purvis 1997); 1.3–5.6 (White 1994: forested part of Lopé N. P., Gabon); 18.4 (Tutin *et al.* 1997: galleries and bosquets in savanna ecotone of Lopé N. P., Gabon); 3.1 (Fa *et al.* 1995: Equatorial Guinea); and 2.0 (Hart, J. A. *et al.* 1996: Ituri Forest, DR Congo). Periodic aggregations on ephemeral resources might explain the higher estimates (see Adaptations).

Adaptations The bright, highly structured colouration and strong pattern of the Red River Hog imply a high premium on intra-specific visual communication; likewise, body stance and positioning of the head and ears are also likely to play roles in visual and social communication. The facial warts of pigs are believed to have evolved in association with tusk length and shape, skull shape and combat patterns between ♂♂. Species with no, or relatively small, warts and short tusks tend to engage in lateral combat postures, whereas species with large warts, large tusks, broad heads and thick skulls tend to use frontal combat postures. Both anatomically and behaviourally, the Red River Hog occupies a somewhat intermediate position between the two types (Frädrich 1974).

Red River Hogs sometimes aggregate into large groups and it is suspected that they migrate long distances (Malbrant & Maclatchy 1949, Abernethy & White 1999). It is at present not certain if such aggregations and migrations are a response to mast fruit crops in the rainforest, as is the case for White-lipped Peccaries *Tayassu pecari* and Bearded Pigs *Sus barbatus*. Observations in the Ituri Forest suggest this may be so: densities in a monodominant *Gilbertiodendron dewevrei* forest near Epulu varied with a factor of 80 (0.1–8.0 animals/km²), with the highest densities occurring during periods when there was a mast crop of *G. dewevrei* seeds. During years with no mast crop, fallen fruit was scarce and during the dry season even almost absent. Densities in a mixed forest type, where variations in fruit abundance were smaller, only varied by a factor of 5 (1.0–5.8 animals/km²) (Hart 2001).

Foraging and Food Omnivores, eating fruits, nuts, seeds, roots and tubers, leaves, fungi, insects, earthworms, small vertebrates and carrion (Carpaneto & Germe 1989, Hart 2001); they also uproot seedlings and saplings. Food items are gathered by walking along and continuously probing the leaf litter and soil with the nose. When visiting a forest clearing at Odzala N. P. in Congo, they spent 53% of

Red River Hog *Potamochoerus porcus* frontal head signals: aggressive (above); submissive (below).

their time feeding, 17% resting and 20% moving about; consumption of roots and herbaceous vegetation (mainly Cyperaceae) occupied 67% of feeding time (Magliocca 2000).

Seeds are a major component of the diet in the Ituri Forest (Hart 2001). They are able to crack open very hard nuts and hard-coated drupes such as *Irvingia* spp. and some Sapotaceae (J. A. Hart pers. comm.). The first sign of their presence is often the sound of nuts and seeds 'exploding' as they are cracked in their jaws, a sound that can be heard up to 200 m away (Abernethy & White 1999, J. A. Hart pers. comm.). Red River Hogs like to root in elephant dung for undigested seeds (Abernethy & White 1999), an activity that occupied 33% of feeding time at a forest clearing in Odzala N. P. (Magliocca 2000). However, the dung is also attractive later in the decay process, when young seedlings come up (J. A. Hart pers. comm.). In Odzala N. P., Red River Hogs mainly foraged for nuts of *Panda oleosa* (Pandaceae) and *Strombosia* sp. (Olacaceae) and for seeds of *Strychnos* sp. (Loganiaceae) (Magliocca *et al.* 2002). Red River Hogs are, therefore, mainly seed and sapling predators rather than seed dispersers; however, seeds of *Uapaca* trees pass through whole and are often found germinating in the dung (Abernethy & White 1999).

In agricultural regions, Red River Hogs will raid crops such as manioc, peanuts and potatoes. Crop raiding becomes more frequent during the main dry season when forest fruit is scarce (Malbrant & Maclatchy 1949).

Social and Reproductive Behaviour Red River Hogs live in family groups, containing ♂♂, ♀♀ and youngsters. Malbrant &

Maclatchy (1949) reported that bands of about 20 were common in Gabon and that large troops could reach 40 individuals; solitary animals are very rare. Elsewhere, Oduro (1989) recorded a mean group size of 10.6 (range 1–15) in Nigeria, while White (1994) mentions a mean group size of 33 in the forests of the Lopé Reserve, and Tutin *et al.* (1997) a mean of 29 in the gallery forests and savanna bosquets of the same park. In Odzala N. P., where both hunting and logging are absent, three groups that visited a clearing during the day were composed of two, seven and three (later joined by a fourth) individuals. During the night a troop of about 40 individuals was observed twice (Magliocca 2000). In Lopé N. P., they sometimes aggregate into groups of more than 100 individuals (Abernethy & White 1999). Groups of 30–60 have been reported from Guinea and the eastern DR Congo (L. Macky & J.A. Hart pers. comm.). In areas with high logging and hunting pressure, Red River Hogs tend to occur in smaller, silent groups active only at night (Abernethy & White 1999). In non-disturbed areas they are also active during the day.

The degree of territoriality, mating system, family relationships and duration of association of adult ♂♂ with ♀♀ are not known. Observations in captivity show that ♂♂ regularly inspect the urine and the anogenital region of the ♀♀ to detect oestrus. The ♂ will follow an oestrous ♀ as she walks around and will regularly nuzzle her vulva, flanks and belly. The ♀ licks the anal and inguinal region of the boar. De Boer (1980) also describes a playful head to head pushing as an element of courtship behaviour. A ♀ that is ready for mating shows the typical immobilization reflex prior to and during mounting. Females leave the group to give birth and lie-up in an elaborate nest, 50–60 cm high and constructed of leaves and twigs (in the forest) and grasses (in savanna regions) (Malbrant & Maclatchy 1949, Abernethy & White 1999). They later re-join the group with their piglets. Red River Hogs are in almost continuous acoustic contact with one another. However, their rich vocal repertoire has never been studied.

Reproduction and Population Structure Analysis of faecal steroid metabolites in captive animals has revealed that reproductive cycles in the Red River Hog start by the end of Dec and last into the summer (Berger *et al.* 2006). In the wild, reproduction indeed appears to be seasonal with most piglets being born at the end of the dry season/onset of the wet season. In Gabon, Malbrant & Maclatchy (1949) found one ♀ with three fetuses in Mar and one with four in Dec. Oestrous cycle length is 34–37 days (Berger *et al.* 2006). An average of 3.4 piglets (range 1–6) is born after a gestation length of 120 days (Macdonald 2000). Piglets weigh 650–900 g at birth and are brown with beige-yellow longitudinal stripes and some spots. The piglets remain tightly huddled in the nest to limit heat loss for the first few days after birth. They soon start to follow the mother while she forages and start to nibble on food items she unearths or that fall from her mouth (Abernethy & White 1999).

Population structure, birth and mortality rates have not been published for wild populations, although Oduro (1989) recorded an immature to adult age ratio of 2 : 1 in groups in Nigeria. In captivity, the oldest zoo-born individual reached an age of 18 years. One wild-caught animal lived at Frankfurt Zoo for 22 years before it died (Winkler 2000, Weigl 2005). However, most individuals probably do not live longer than 15 years (Winkler 2000).

Predators, Parasites and Diseases In rainforest habitat, Leopards *Panthera pardus* prey on adult individuals (Hart, J. A. *et al.* 1996, Abernethy & White 1999), and Red River Hogs made up 20% of the biomass consumed by Leopards in Lopé N. P. (Henschel *et al.* 2005) and up to 50% in Ivindo N. P., Gabon (Henschel *et al.* 2011). Other potential predators include Lions and Spotted Hyenas (Abernethy & White 1999, Breuer 2005), while Robust Chimpanzees *Pan troglodytes* (Alp 1993, Abernethy & White 1999), large pythons and large raptors prey on piglets. Male Red River Hogs fiercely protect themselves and their group members from carnivores and can win a fight with a Leopard (A. Gautier-Hion pers. comm.). Like Bushpigs (Anderson *et al.* 1998), Red River Hogs are most likely vectors for African swine fever and allegedly also trypanosomiasis, and are an intermediate host for trichinosis (Vercammen *et al.* 1993). Ntiemo-Baidu *et al.* (2005) recorded the ixodid ticks *Ixodes cumulatimpunctatus*, *Rhipicephalus cuspidatus*, *R. lunulatus*, *R. simpsoni* and *R. ziemannii* on animals in Ghana.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although generally widespread and abundant, increased hunting pressure (for subsistence purposes, as an agricultural pest or because it is a vector of livestock diseases, and also for the commercial bushmeat trade) has made the species rare outside protected areas in a number of countries, particularly in the west and north of its range (Vercammen *et al.* 1993, Abernethy & White 1999). At the bushmeat market of Basankusu, DR Congo, 38% of the 13,831 carcasses recorded in 276 counting days were artiodactyls and of these 21% were Red River Hogs (J. Dupain pers. comm.). Seventy-eight per cent of hunters interviewed in Gabon by Lahm (1991) cited the sale of Red River Hog meat as among their most important sources of revenue; only about one-third of their gained bushmeat

was retained for domestic consumption. Consequently, hunting has led to direct declines in abundance in, for example, the forests of S Gabon (Laurance *et al.* 2006); however, Red River Hogs seem to stand up to hunting pressure relatively well in other regions (e.g. DR Congo; J.A. Hart pers. comm.), although this requires further study.

Measurements

Potamochoerus porcus

HB (♂ ♂): 1113 (1030–1190) mm, n = 6

HB (♀ ♀): 1070 (940–1170) mm, n = 11

T (♂ ♂): 433 (405–455) mm, n = 6

T (♀ ♀): 418 (395–435) mm, n = 8

HF c.u. (♂ ♂): 242, 260 mm, n = 2*

HF c.u. (♀ ♀): 235 mm, n = 1*

E (♂ ♂): 190, 205 mm, n = 2*

E (♀ ♀): 180 mm, n = 1**

WT (♂ ♂): 63.0 (51.0–80.0) kg, n = 6

WT (♀ ♀): 43.5 (33.0–56.0) kg, n = 11

Gabon (Malbrant & Maclatchy 1949)

*AMNH (D. Lunde pers. comm.)

**MRAC (W. Van Neer pers. comm.)

Record tusk length is 279 mm for an animal from Gabon (Rowland Ward)

GENUS *Hylochoerus*

Forest Hog

Hylochoerus Thomas, 1904. Nature 70: 577.

Hylochoerus is a monospecific genus, represented only by the Forest Hog *H. meinertzhageni* that has been, from the first, recognized as generically different from any other type of pig. The teeth and skull, in particular, differ in many ways from those of other, rootling suini

such as Wild Boars *Sus scrofa*, or bushpigs of the genus *Potamochoerus* (Ewer 1958, Harris & Cerling 2002). None the less, the functional significance of these peculiarities was not well understood at first (Thomas 1904).

In the century since the Forest Hog was first described, many suid fossils have been discovered and some of these, notably fossil skulls of the polymorphic *Kolpochoerus heseloni*, have helped illustrate the evolutionary divergence, within Africa, of this genus from a more

Forest Hog *Hylochoerus meinertzhageni* head of female (left) and male (right).

LEFT: Forest Hog *Hylochoerus meinertzhageni* head: above, superficial myology; below, cross-section showing digastric muscle.

ABOVE: Diagram of upward flexion in Forest Hog *Hylochoerus meinertzhageni* skull from less elevated ancestral condition (from Kingdon 1979).

typically suid ancestry. White & Harris (1977) have suggested that *Hylochoerus* derived during the Pleistocene from the Plio-Pleistocene fossil pig lineage *Kolpochoerus*. When correlated with known behaviour, ontogenetic growth patterns and with evolutionary changes manifest in the skulls of fossil pigs, almost all the unique features of *Hylochoerus* cranial anatomy can be attributed to a relatively recent change in diet (Ewer 1970, Kingdon 1979).

Unlike their closest, rootling relatives, *Hylochoerus* are surface-cropping animals, harvesting herbs and grasses with their capacious mouths and broad, sharp-edged lips. The teeth have also been modified for such cropping but all these changes are likely to have been relatively late, Pleistocene, developments (Harris & White 1979) and manifest quite clumsy improvisations in the service of a relatively new mode of mastication superimposed upon an older suine pattern. It can be shown that alterations in the balance of masticatory muscle forces and muscle attachments have led to expansions, contractions, tilts and bucklings in the skulls of *Hylochoerus*.

Typically, suine molar teeth have thick enamel cusps that are well suited to crushing large fibrous material, such as roots, and cement is virtually absent in such hard, compact teeth. Rootling pigs have six teeth aligned down a long, relatively narrow tooththrow that champs up and down in a predominantly vertical action. This exerts little or no lateral pressure on the teeth. By contrast, *Hylochoerus* have higher crowns with thin dentine and enamel spaced out within a thick matrix of cement (Ewer 1970). Wear on such teeth produces sharp ridges and this creates the sort of milling surfaces typical of leaf-eating teeth. However, instead of retaining a complete tooththrow of six chewing teeth, *Hylochoerus* juveniles begin with a row of five teeth, the anterior ones of which are soon shed. This attrition of the premolars (and eventually of the first molar, too) is due to *Hylochoerus* masticating its food with a significant sideways action. This lateral action exerts more movement at the front end of the tooththrow, less at the back. It is clear that the small premolars are ill-suited to withstand the pressure and lateral chewing effectively wears away and gouges out the premolars at a relatively early age.

The main power for this novel type of jaw movement comes from the pterygoid muscles that attach the lower mandible to the roof of the mouth (see Kingdon 1979). To operate effectively these muscles (which are exceptionally well developed in *Hylochoerus*) have several requirements: (1) an increase in the amplitude of their partly lateral action; (2) enlarged muscle size; and (3) an increase in their areas of attachment to the mandible and pterygoid. In addition to these changes, the abandonment of rootling in favour of cropping has greatly diminished the need for powerful leverage at the occiput, which is broad, but very short in *Hylochoerus*. The most obvious results of these alterations have been to broaden the back of the skull and bulk out the region immediately behind the tooththrows. These changes, in turn, have had the phylogenetic effect of lifting the entire tube of the muzzle in relation to the basicranial axis, making the Forest Hog skull, relative to that of a rootling pig, more of a horizontal tube than a diagonal wedge. These functional changes in core regions of the skull's interior have remoulded the plastic, malleable surfaces of the skull's outer shell. Thus, the area between and immediately anterior to the eyes has been forced to 'buckle' outwards as the muzzle lifts. Shrinkage of the occiput has caused the forehead region to cave in and create a deep concavity above the cranium.

The skull of *Hylochoerus* is, therefore, an outstanding example of how changes in a single parameter, in this case diet, have far-reaching effects on cranial structure. The likelihood that these innovations are quite recent suggests that some characteristics, such as early loss of premolar teeth, merely represent incomplete accommodation, by an earlier format, to entirely new challenges. Those challenges would seem to have included an increase in the extent and predictability of formerly closed forests as they became more fragmented, perforated or degraded by a variety of forces, notably drier, colder climates, the actions of elephants, humans and falling trees, and the spread of low-level herbage and grasses in lacunae within these moist habitats. *Hylochoerus* is not, therefore, perfectly adapted to its niche but can, in some respects, be described as the cobbled-together descendant of a lineage that abandoned successful earlier adaptations in response to changing circumstances.

Jonathan Kingdon

Hylochoerus meinertzhageni FOREST HOG (GIANT FOREST HOG)

Fr. Hylochère; Ger. Riesenwaldschwein

Hylochoerus meinertzhageni Thomas, 1904. Nature 70: 577. Kenya, 'Nandi Forest, near the Victoria Nyanza, at an altitude of 7000 feet'; near Kaimosi [2134 m].

Forest Hog *Hylochoerus meinertzhageni*.

Taxonomy Despite its large size, the Forest Hog was the last wild pig – and one of the last large mammals – to be discovered in Africa. Between 1904 and 1930 seven subspecies were described, but recent taxonomic reviews (Ansell 1972, Grubb 1993b, 2005) only recognize three subspecies. The validity of one subspecies, *H. m. schulzi*, has been refuted by Mohr (1942), and shown to be a synonym of *Potamochoerus larvatus hassama* (Grimshaw 1998, Kock & Howell 1999). Pigs of this genus therefore belong to a single extant, polytypic species. Originally named Forest Pig, *Hylochoerus* was later qualified as 'Giant' Forest Hog, in reference to its great size in comparison with other wild pigs. However, it has been shown that only the nominate subspecies, *H. m. meinertzhageni*, truly deserves this epithet. All living *Hylochoerus* populations are substantially smaller than their prehistoric ancestral stock. Synonyms: *gigliolii*, *ituricus*, *ituriensis*, *ivorienensis*, *rimator*. Chromosome number: $2n = 32$ (Melander & Hansen-Melander 1980).

Description A large, heavily built pig covered in long black hair. Hair thickness, length and colour vary with age and location: the dorsal and lateral pelage is thick and dark brownish-grey to coal-black; 'whiskers' on jaw-line callosity white to yellowish; ventral pelage sparse and greyish to black. There is a dorsal crest of long, thick erectile hair. Hairs thick, oval in cross-section, and often split.

Lateral, palatal and dorsal views of skull of Forest Hog *Hylochoerus meinertzhageni*

Forest Hog *Hylochoerus meinertzhageni* (female) skeleton.

Forest Hog *Hylochoerus meinertzhageni* (female) myology.

Broad, pointed ears fringed with black hair. Small orange-brown eyes, but very pale irises also occur, possibly reflecting nutritional or social stress (J. Kingdon pers. obs.). Adult boars significantly larger than ♀♀, with a more bulky body and massive head; a dish-like depression over the forehead is surrounded by a circle of bony crests covered with bare skin. Zygoma are thickened and pneumatized, supporting inflated and naked infraorbital swellings. In boars these swellings commonly become stained with exudates from the preorbital glands which drain from a deep tear duct. The broad, flat snout ends in a very wide (10–15 cm), oval and swollen rhinarium with nostrils set wide apart. Legs robust (but can look spindly by comparison with the body mass); hooves large and rounded. Tail slender, flattened at its end, with long sparse bristles implanted laterally. Piglets are plain coloured, although dark-brown individuals with light-brown stripes have been reported (Grubb 1993b). Females have two pairs of nipples.

The skull is broad when compared with that of *Potamochoerus*. Structure of the skull and facial musculature adapted to a folivorous rather than an omnivorous diet (Ewer 1970; for dissections and diagrams see Kingdon 1979). The dental formula is $I^{1/3}, C^{1/1}, P^{2/1}, M^{3/3} = 30$; the single pair of upper incisors is often shed in adults. Tusks flare out horizontally and curve backwards in the same plane as the face. Dentition is hypsodont and much more specialized than in *Potamochoerus*, with molar cusps of the crown spaced out within a thick matrix of cement and sharp transverse ridges between enamel pillars. The anterior cheekteeth tend to be lost with age.

Geographic Variation Three subspecies are provisionally retained, but most specimens appear to represent variants in a polymorphic species. Smaller specimens predominate in the western and central lowland forests, heavier ones in highland forests, east of the Rift Valley.

H. m. ivoriensis: isolated populations from Guinea to S Ghana. Does not differ significantly from *H. m. rimator* in dimensions or features (length of skull in ♂♂ is 35.5–39.7 cm, and 33.3–37.2 cm in ♀♀; Grubb 1993b), but the shape of the skull is distinctive and unlike that of other subspecies.

H. m. rimator (includes *ituriensis*): SE Nigeria to E DR Congo. Specimens from the western part of the range are on average smaller (length of skull 34.1–38.8 cm in ♂♂, and 33.0–37.7 cm in ♀♀; Grubb 1993b) than those from further east (length of skull 36.6–49.5 cm in ♂♂, and 31.4–43.9 cm in ♀♀; J.P. d'Huart, pers. obs.). Distinctly smaller and lighter than *H. m. meinertzhageni*, with more brown and yellowish hair in pelage.

H. m. meinertzhageni: scattered populations from Albertine Rift Highlands of E DR Congo to Kenyan Rift Valley. Resembles *rimator* in shape of skull, but nominate race differs in its jet black pelage, larger size (length of skull 41.0–46.1 cm in ♂♂ and 38.1–42.7 cm in ♀♀; Grubb 1993b) and size of the tusks. The cheekteeth are also different in that the cementum is developed at the expense of the enamel pillars, which are more widely separated (Grubb 1993b). Intergradation between the lowland forest *rimator* and this large highland race presumably occurs along the foothills of the Albertine Rift (Grubb 1993b).

It is probable that Ethiopian Forest Hogs are derived from a common stock with *meinertzhageni*; however, given a wide separation of these two populations by a well-established eco-climatic boundary, d'Huart (1978) and Yalden *et al.* (1984) have suggested that it is possible that the Ethiopian population comprises a different, as yet undescribed, subspecies.

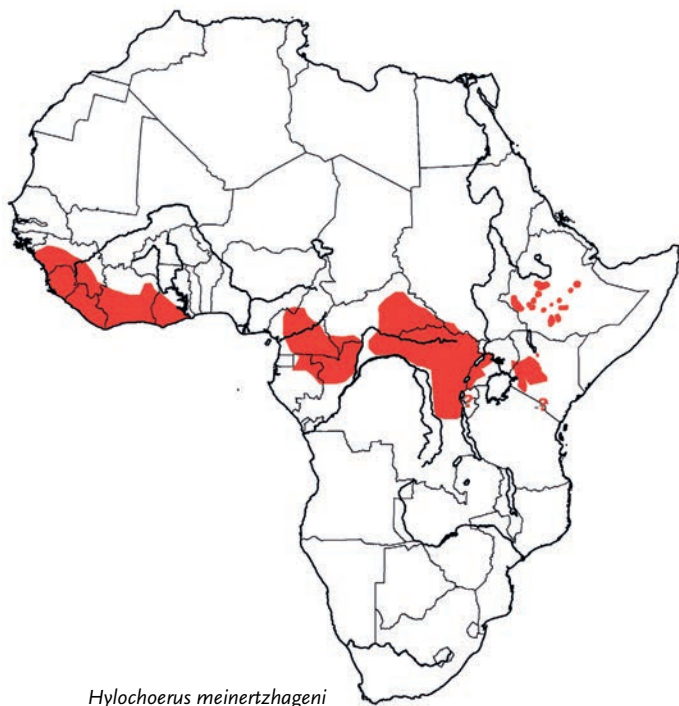

Similar Species

Potamochoerus larvatus. Sympatric in some localities in eastern Africa.

Smaller and more compact, with pale pelage on face and nuchal/dorsal crest; snout less swollen.

Distribution Endemic to Africa. Unevenly distributed in scattered populations throughout undisturbed tracts of lowland rainforest in West Africa and on the right bank of the Congo R. Also present in transition gallery forests in the Guinean savanna zone, in highland mixed forests of Albertine Rift, and in isolated montane forests in Kenya and Ethiopia. Their range resembles that of the Bongo *Tragelaphus eurycerus*, which also exploits unstable forest-edge mosaics.

In West Africa (S Guinea, Liberia, S Côte d'Ivoire, S Ghana), the range of *H. m. ivoriensis* now roughly corresponds with the least

*Hylochoerus meinertzhageni*

disturbed remnants of the lowland humid forest. The species may occur in other parts of Guinea, Sierra Leone and Côte d'Ivoire in montane forests (e.g. Mamou Mts, Foutah Djallon, Loma Mts) and in gallery forests (Outamba N. P., Comoé N. P.), but many records remain unsubstantiated (e.g. see Grubb *et al.* 1998). Forest Hogs have been extirpated from many intervening sites that connected primary forest and Guinean savanna. Their present distribution has become increasingly fragmented, though the full extent and pace of this process is difficult to document because this species is a premium target for the rapidly expanding bushmeat trade. Reports from Senegambia, Guinea-Bissau and Togo are unsubstantiated (Grubb 1993b, Grubb *et al.* 1998).

Western populations of *H. m. rimator* (those between the Rivers Niger/Bénoué and Congo/Oubangui) still occur in five countries from the Nigeria/Cameroon border to N Gabon, N Congo and SW Central African Republic. The species is absent from Bioko I. and is believed to be extinct in the vicinity of Rio Muni in Equatorial Guinea. Forest Hogs have also disappeared from many areas in W Gabon and S Congo. Further east, this subspecies remains almost continuously distributed along the right bank of the Congo R. to the southernmost limits of the equatorial forest in E DR Congo in the south, to extreme N and NE DR Congo, E Central African Republic and SW Sudan in the north. It occurs in all types of primary, secondary and gallery forests. The northern limit of its range is in the vicinity of Massif des Bongo, south of Manovo–Gounda–St Floris N. P. in Central African Republic, where the progressive fragmentation of the forest galleries is likely to isolate this population in the future. This subspecies has disappeared from several sites in N Central African Republic and NW DR Congo.

In the easternmost limits of the Forest Hog's range (along the west branch of the Rift in E DR Congo, W Uganda and Rwanda, and along the east branch in E Uganda, W and C Kenya), the 'giant' form, *H. m. meinertzhageni*, now survives only in isolated montane forests, from 900 to 3800 m. There have been no records of *Hylochoerus* from

Rwanda since the late 1980s (B. Dowsett pers. comm.), but they may possibly survive in Nyungwe Forest. In the absence of reference specimens or photographic records, Forest Hogs are no longer considered to occur in Tanzania (Grimshaw 1998, Kock & Howell 1999). Some connecting corridors still exist within the complex of protected areas from the Rwenzori Mts in the north to the Virunga Mts in the south, but most of the remaining populations in this region are now isolated. A similar situation occurs in SC and WC Ethiopia (d'Huart & Yohannes 1995), where fragmented subpopulations are well isolated from the nearest neighbouring populations of Sudan, Uganda and Kenya.

Habitat In common with the Red River Hog *Potamochoerus porcus*, the Forest Hog is more dependent on forest than other African suids. Throughout its range, it inhabits a wide variety of forest types, ranging from sub-alpine areas and bamboo groves through montane to lowland and swamp forests, galleries, wooded savannas and post-cultivation thickets. Within these habitats, it occurs preferably where there is a convenient and permanent water source, thick understorey cover in some parts of the home-range, and a diversity of vegetation types.

In E DR Congo and W Uganda, the Forest Hog is an ecotone species, preferring intermediate habitat zones where the edge effect is maximized and where resources from different vegetation types can be exploited within a limited area. This was well illustrated in Budongo, Uganda, where Kingdon (1979) mapped a 1600 km² block of mixed wooded grasslands, forest, forest/ woodland mosaics and cultivation where he established the local ecological separation of *Hylochoerus*, *Potamochoerus* and *Phacochoerus*. The former shared habitat with one or other, or both species in areas where uniform forest and grasslands abutted, but *Hylochoerus* became dominant only in areas of extensive forest/grassland mosaic. In the Aberdare Mts in Kenya, the Forest Hog was extremely abundant during the 1970s and, over a period of five years (1970–1974), a total of many hundreds of sightings were recorded visiting Yathabara glade (a major waterhole/salt-lick in the Aberdare Mts of C Kenya). By contrast, there were only two sightings of Bushpigs *P. larvatus* and it is possible that competition for secure shelters (within a montane forest that was freckled with numerous small, grassy glades) might

Forest Hog *Hylochoerus meinertzhageni*.

have been the primary cause of this imbalance between species (Kingdon 1979).

In the central plain of Virunga N. P., Forest Hogs inhabit forest galleries (dominated by species of the genera *Croton*, *Pterygota* and *Rauwolfia*), dry forests (*Euphorbia*, *Olea*) and bush thickets (*Capparis*). These three habitats constitute a sequence in the natural succession from forest to savanna, and the hogs move between them, making full use of their resources. During the 1980s and early 1990s, Forest Hogs from forested areas of the central part of Queen Elizabeth N. P. (Uganda) increased and extended their range into grassland/thicket mosaic areas, including the Mweya peninsula (Viehl 2003, Klingel & Klingel 2004a, b). In dense forest areas, Forest Hogs tend to concentrate in inselberg mosaics of savanna and forest, around clearings, or in mixed forest patches rather than in monodominant forest (Hart 2001).

On a continental scale, the variety of forest habitats occupied implies a high degree of adaptability to local climatic conditions. Forest Hogs live in cold uplands (where night temperatures may fall to 0°C) as well as hot lowlands, but do not tolerate low humidity or prolonged solar radiation. Extreme mean annual rainfalls in *Hylochoerus* habitat vary from 800 mm in Masai Mara National Reserve to 3200 mm in W Liberia.

Abundance A 1990 IUCN questionnaire survey suggested that this species had a restricted distribution at low density over most of its range, but was 'widespread at low density and locally abundant' in Guinea and Côte d'Ivoire, and 'widespread at high density' in Congo. The value of such assessments is obviously limited without further detail and validation, and, in any event, hog abundance has been widely reported to fluctuate over time (due to rinderpest outbreaks, and increases or declines in the number of predators). Until recently, the only explicit population density estimates came from DR Congo and these ranged from 0.4/km² in Garamba N. P. to 2.6/km² in the central plain of Virunga N. P. (d'Huart 1978). Local population densities may be much higher though, since these estimates were based on spot counts over large areas. Between Sep and Oct 1975 Kingdon (1979) estimated about 70 individual forest hogs coming into Yathabara glade from an estimated catchment area of about 70 km² (a density of about 10/km²). Since that time (when the density of this species was thought to have been the highest ever known in the area), Forest Hogs are known to have declined throughout the Aberdare Mts, primarily due to an influx of Lions *Panthera leo* (Klingel & Klingel 2004b); the neighbouring hog population on Lion-free Mt Kenya has seen no such decline.

A 1998 count of known individuals on the very localized Mweya Peninsula, Queen Elizabeth N. P., gave a density of 9–13/km² (H. Klingel pers. comm.). However, Klingel & Klingel (2004a) subsequently recorded a 30% fall in the density of Forest Hogs on the Mweya Peninsula; in two other study areas, the decline was 70–80%. The main cause of decline was predation by Lions, Spotted Hyaenas *Crocuta crocuta* and Leopards *Panthera pardus*, with competition from other herbivores, nutritional stress, diminished reproductive recruitment, emigration and road kills given as further causes. A 1999 sample transect census of Jibat Controlled Hunting Area near Ambo, Ethiopia, suggested a figure of 8.25/km² (F. Kebede pers. comm.). Comparable densities emerged from the frequency of observations and recorded group sizes in areas of suitable Forest Hog

Forest Hog *Hylochoerus meinertzhageni* tooth succession from left: juvenile, adult and aged adult.

habitat in Virunga N. P. and Queen Elizabeth N. P. (K. Viehl pers. comm.).

Seasonal mass movements have been noted in forest clearings in N Congo (R. Ruggiero pers. comm.), and also in the Epulu Forest (Hart 2001). These have been attributed to masting cycles or similar fluctuations in the availability of grasses and other foods. Other explanations have been proffered, but documentation has been poor.

Adaptations Features of fossil ancestors of *Hylochoerus* show that grazing is a relatively late development in this species and that some members of its ancestral lineage may have been substantially larger than the living species. Grass-eating has involved the need for powerful lateral chewing, and shaped the molars in a unique design (Bouet & Neuville 1930). These molar adaptations are very distinct from, and somewhat intermediate between, those of *Phacochoerus* and *Potamochoerus*. In the course of evolution the muscles and bony anchorage needed to support this has caused massive realignments in the skull (Ewer 1970, Kingdon 1979). The most significant of these has been the role of greatly enlarged pterygoid muscles (which serve side to side mastication). This enlargement appears to have acted as an 'evolutionary wedge' opening up the base of the skull, lifting the muzzle and buckling the external bones of the forehead. Thus, the external modelling of the Forest Hog's forehead can be attributed to evolutionary changes in diet and masticatory function (see diagrams in Kingdon 1979).

Forest Hog *Hylochoerus meinertzhageni* underside of lower jaw.

The Forest Hog's huge bulbous rhinarium is rarely used for rooting; unlike *Potamochoerus*, its prenasal bone is progressively losing its mobility by fusing with the intermaxillary septum, making the massive snout quite unsuited for excavating food from hard soil. By discarding use of the rhinarium for digging in all but the softest soils, the Forest Hog's mouth has adapted more fully to grazing, involving a reshaping of

the lips, the tusks and the nasal disc. Skull features are well adapted to competitive and fighting techniques by involving two different, often sequential, forms of frontal combat (Kingdon 1979, Estes 1991a). In the 'snout-ramming/knocking' phase adult and subadult ♂♂ join their broad nasal discs with heads horizontal and then test their weight and strength by pushing; during sparring matches between young ♂♂, both snouts are often pushed upwards, but contestants also deliver sideward blows and try to push the opponent's snout to the side. This form of contest is facilitated by the slightly bulbous, flat-fronted nasal disc and the reinforced median wall of the snout. In the 'forehead butting' phase mature ♂♂ depress their heads and press their massively reinforced foreheads together and push until one withdraws. Sometimes contestants charge each other from a distance, in which case a very loud cracking noise can be produced should their foreheads clap together in exact opposition and thus compress air between their cupped foreheads. Thick protective tissues on the cheeks, heavy hollowed ridges round the forehead and zygomatic arch, a 'double-hulled' cranium (see Kingdon 1979) and the wide curving angle of the tusks can absorb or deflect the impact of these powerful clashes, but skull fractures, and occasionally deaths, can and do occur.

The comparatively thick skin and coarse pelage with sparse hair (intermediate between the dense pelage of *Potamochoerus* and the bare skin of *Phacochoerus*) are adaptations that allow Forest Hogs to live in extreme environmental conditions both in closed and open habitats. Their activity patterns and feeding behaviour are adapted to both open and forested areas. In the grassland/bushland/dry forests mosaic of Virunga N. P., Forest Hogs spend on average 25% of their daily time moving and foraging in savanna, 21% moving, foraging and wallowing in thickets or forested areas, and 54% resting in a sleeping site in the same habitat (d'Huart 1978). In lowland forest (notably in the Maya clearing of Odzala N. P., Congo), Forest Hogs spend 44% of the time feeding, 14% moving and 31% resting (F. Magliocca pers. comm.). In Queen Elizabeth N. P., during the wet season, the hogs feed during the day (as well as wallowing) and sleep at night, whereas they spend much of the day and part of the night feeding during the dry season, particularly if fresh growth is scarce, and may retreat to the lake-side when drought becomes extreme (Klingel & Klingel 1999). In the montane forest of Aberdares N. P., Kenya, the frequency of daylight sightings in Yathabara glade (from 5% to 27% in 1974) is inversely correlated with temperature; daylight foraging was commonest between Apr and Nov and minimal during the hot season, between Dec and Mar (Kingdon 1979). In the salines of Odzala-Kokoua, Nganongo (2000) observed the hogs wallowing in mudpools during the heat of the day, confirming this species' intolerance of prolonged direct exposure to the sun. Social activity in Forest Hogs is strongly influenced by climate and season. Klingel & Klingel (2004b) found all members of family groups joined up in the wet season, stayed close together and synchronized activity when they rested, wallowed or walked, whereas they could split up, sometimes for several days, during the dry season.

Foraging and Food Mainly a grass-eater and folivore. Field observations of feeding habits clearly document that Forest Hogs are by no means pure grazers. Depending on the seasonal content, stage of growth, and quantity of plant resources available in the various portions of their territory, they seem to display a great versatility

in the selection of their food. Both in montane areas and forest/grassland mosaics, many species of grasses, sedges and herbs are cropped. Forest Hogs rootle very much less than other wild pigs and dig only in very soft or muddy soils.

In Queen Elizabeth N. P., on the Mweya Peninsula, Giant Forest Hogs eat 46 of the 115 plant species that have been recorded there (Klingel & Klingel 2004a). In a savanna area of the same park, Forest Hogs were found to select more than 100 food plants and show a high flexibility in choice (Viehl 2003). In central and East Africa, Forest Hogs prefer to browse herbaceous growth or graze on mats of relatively short green grass. Among the monocotyledons, several species of Commelinaceae and Cyperaceae are grazed in addition to a large number of Gramineae. The selected dicotyledons include, among others, numerous species in the families Acanthaceae, Amaranthaceae, Compositae, Convolvulaceae, Euphorbiaceae, Melostomaceae, Portulacaceae, Urticaceae and Salvadoraceae (Rahm & Christiaensen 1963, d'Huart 1978, Kingdon 1979).

Studies on grass preferences in Virunga N. P. show that five major savanna species (*Cynodon dactylon*, *Sporobolus pyramidalis*, *Panicum repens*, *Cenchrus ciliaris* and *Chloris gayana*) were selected on a yearly average during 94% of grazing time (d'Huart 1978). Seasonal preferences by *Hylochoerus* for these grasses is less marked than those shown by *Phacochoerus* in contiguous Queen Elizabeth N. P., but the same grasses are selected by both pigs during the same periods (Field 1970b, d'Huart 1978). However, preferences for the same grasses are not repeated during each of both dry and wet seasons. In Virunga N. P., an order of preference (the same for both dry and wet seasons) was established by correlating the frequency of selection time with the protein and carbohydrate content of the grasses; these data showed that hogs select grasses when their nutrient and energetic content is highest (d'Huart 1978). A study on carbon isotopic composition of *Hylochoerus* hair from the Mweya Peninsula has confirmed this observation, estimating that Forest Hog diet actually comprised more than 95% of C₃ dicotyledons over much of the year, but that the proportion of C₄ grasses rose up to 25% in the wet season (Cerling & Viehl 2004). Young piglets are known to feed on grasses well before weaning.

In dense forest both Forest Hogs and Bongos feed on mast seed in monodominant *Gilbertiodendron* stands in N Congo, but not in E DR Congo (Hart 2001). Of the time hogs spent (mainly in water-logged areas) in a forest clearing in Odzala N. P., 44% was spent feeding on herbaceous plants from hydromorphic areas; these plants, *Enhydra fluctuans*, *Paspalum conjugatum*, *Ludwigia stolonifera* and *Rhynchospora corymbosa*, were significantly richer in calcium and nitrogen than those growing in non-preferred ones and it was concluded that mineral-rich forage was the essential reason for hogs to visit the natural clearings (bais) (actual drinking was never observed; F. Magliocca pers. comm.).

Examination of adult hog dung by various authors has revealed a variety of different materials, including poorly masticated grass stems and leaves, fragments of *Iulus* sp., shields of ticks (*Amblyomma* spp., *Rhipicephalus* spp.), earth, Forest Hog bristles and so forth. The animals seek salty earth, which they excavate with their tusks and their lower incisors; salt-licks may include termite mounds, shallow caves, dry river banks, or even the embankment of a deserted road. Occasionally, they eat meat and bones of carrion, eggs and larvae (Kingdon 1979). Coprophagy is not common, but piglets are fond of fresh elephant dung when available.

Social and Reproductive Behaviour Forest Hogs live in relatively stable, non-territorial family groups (or 'sounders') consisting of one to three (occasionally four) ♀♀ and their young, and a dominant adult ♂. In Queen Elizabeth N. P., group sizes range from 2 to 19 individuals (very occasionally up to 24), with an average of 11.2 (Klingel & Klingel 2003, 2004b, H. Klingel pers. comm.). In contiguous Virunga N. P., average group size was 13.9 (d'Huart 1978). During the early 1970s in the Aberdare Mts, groups numbered 2–18 (average = 6.6); however, it was rare for more than four or five adult ♀♀ to associate for any length of time.

In the Aberdares population some individual boars maintained a stable relationship with a group of ♀♀, but some were effectively ousted during amalgamation episodes that were probably brief and may have been the direct product of convergence on a common resource, namely the artificial mineral lick in Yathabara glade (Kingdon 1979). These short-term displacements might give some support to the theory that dominance hierarchies may exist among ♂♂ observed within the same 'group'. Such 'groups', with up to four adult ♂♂ and at least eight adult ♀♀, have been recorded, but field observers agree that a single dominant boar does not accompany a sounder with more than four sows for any durable span of time. This may be primarily due to a weakening, as group size increases, of the familial bonds that tie sows to one another. Large groups consistently split into smaller groups and into small family units with a single boar predominating.

Generally, only alpha-males have access to the ♀♀, but copulations with peripheral individuals do occur outside the group (d'Huart 1978). In Virunga N. P., male tenures were recorded to last up to four years (d'Huart 1978), but in neighbouring Queen Elizabeth N. P., Klingel & Klingel (2004b) found the longest male tenure reached seven years. These researchers found infanticide was common immediately after a new ♂ joined a group, in spite of all ♀♀ attacking the boar when he pursued any of their offspring (Klingel *et al.* 2001). Paradoxically, such risk to their young must strongly favour females' maintenance of a long-term, stable relationship with one ♂. That this must be so is strongly implied by both sexes taking part in group defence, and by group cohesion being independent even of the alpha-male's physical presence (Klingel & Klingel 1999). Depending on local group dynamics or the overall density of hogs (particularly the relative numbers of adult ♂♂), the durability of male domination over specific groups of ♀♀ might vary or fluctuate from one locality or period of time to another, but the prevalence of infanticide, as revealed by the Klingels' studies, must strongly favour stable family groups (Fimpel 2002). In the Aberdares, between 1970 and 1974, Kingdon (1979) thought that, in general, groups of ♀♀ were not strongly attached to a single boar, but the apparent turnover of ♂♂ attending female groups might have been a local and temporary by-product of a very rapid hog population increase and equally rapid decline over the period of observation.

All studies have concurred that the *core* group of up to four adult ♀♀ is always stable, even in the absence of a dominant ♂; furthermore, with the exception of the alpha-male, all members of the group are directly related to each other. Indeed, younger ♀♀ patiently wait for aged sows and respond to the latter's 'lost' calls (Klingel & Klingel 2004a). While young ♀♀ stay all their life in the group, subadult ♂♂ leave it voluntarily at the age of 2–3 years and form small temporary bachelor groups until they can compete for

Forest Hog *Hylocherus meinertzhageni*.

the possession of ♀♀ and form their own sounder (d'Huart 1978, Klingel & Klingel 2004a). There are considerable fluctuations in the proportion of solitary animals, with a range of between 15% and 48% of all groups (in which singletons scored as a 'group') recorded at Yathabara glade. The number of Yathabara singletons, mostly boars, consistently peaked during periods of high temperature and declined, often very rapidly, when temperatures dropped (Kingdon 1979). A yearly average estimate of singletons among all hog sightings in Virunga N. P. was 17% (d'Huart 1978).

Occasionally, several groups gather and stay together for a few hours forming aggregations of up to 40 or 50 individuals (d'Huart 1978, Kingdon 1979). It is possible that under such circumstances the bonds between certain individuals and their original group break down and new links are formed. These transfers would effectively scramble the individual composition of groups, but Klingel & Klingel (1999, 2004a) have established that female groups are consistently made up of close relatives. Fights between ♂♂ for possession of groups give the impression of being unritualized frontal combats between bachelors or alpha-males from other groups (but see discussion under 'Adaptations'). These fights can result in severe injuries, including skull fractures (see Kingdon 1979) and male–male wounding can lead to significant mortality (d'Huart 1978).

Contacts between groups were rarely observed in Virunga N. P., but when they did occur interactions between individuals from neighbouring groups were usually peaceful and dominated by reciprocal curiosity (d'Huart 1978). In Queen Elizabeth N. P., antagonism between groups is not uncommon in the dry season and takes the form of female-on-female running chases followed by retreat (Klingel & Klingel 2004a). Such fights notwithstanding, neighbouring groups usually actively avoid contact. Young ♂♂, instead, are prone to frequent fights and fights between rival bachelors can go on for weeks; Klingel & Klingel (2004b) recorded as many as 40 head-on collision-fights in just 10 minutes!

Forest Hogs are not territorial as Mohr (1960) once suggested. Home-ranges were estimated to cover an area ranging from 2 to

5 km² in Virunga N. P. (d'Huart 1978). In Queen Elizabeth N. P., Klingel & Klingel (2004a) found that home-ranges covered several square kilometres with very extensive areas of overlap. At Yathabara glade the relative frequency with which particular groups were seen at the waterhole/salt-lick implied a graduated series of multiple, overlapping ranges, with those living nearest the glade being the most frequent visitors and the most distant ones the least frequent (Kingdon 1979). Rahm & Christiaensen (1963) estimated ranges of 7.5 km² in Kahuzi-Biega N. P., DR Congo. Although home-ranges are not marked or defended as territories, and neighbouring groups share at different times the use of the same elements (tracks, wallow, salt-licks, latrines), hogs do defend core areas during periods when food is scarce, as it often is during the dry season; adult ♀♀ are particularly defensive (Klingel & Klingel 2004b).

Dung is seldom dropped at random; favoured dung-sites are generally located at the base of a tree, under a thicket, or around a termite mound. The largest and most frequently used dung deposits are communal 'latrines' situated along access paths around the sleeping sites. The size and number of latrines near sleeping sites depend on the frequency with which the place is used and the size of the contributing group. For the positioning of latrines around typical sleeping sites see sketch-maps in Kingdon (1979).

Courtship is rough and noisy; once the boar has identified an oestrous ♀ he keeps close to her, grunting loudly, urinating frequently and butting her hindquarters and flanks with snout or forehead until she finally stands. Copulation lasts from 1 to 10 min. Females isolate themselves from the group for 2–5 days to give birth, and piglets are born in a dry nest under a dense bush or a stack of branches or hay. They stay close to their mother and suckle standing up (sometimes, and momentarily, while walking) and the piglets respect a teat order (K. Viehl pers. comm.). Lying down and allosuckling are uncommon. Female hogs have been reported to be rather careless mothers, and piglets are frequently kicked, pushed or stepped on (Schneider & Viehl 2000).

Forest Hogs have a wide range of vocalizations, including snorts, grunts and squeals; Fimpel (2002) and Klingel & Klingel (2004a) have recorded 18 different types of call, implying a highly differentiated auditory communication repertoire. Occasionally, Forest Hogs display aggressive and bold behaviour and family groups are known to chase away Leopards, Common Hippos *Hippopotamus amphibius*, Bongos and African Buffalo *Syncerus caffer*. However, they also graze peacefully next to African Buffalo, Savanna Elephants *Loxodonta africana* and various antelopes at Yathabara glade. In central Africa they commonly accompany Forest Elephants *Loxodonta cyclotis*, Western Lowland Gorillas *Gorilla gorilla gorilla* and African Buffalo on marshy bays (J. M. Froment pers. comm.), as well as Sitatungas *Tragelaphus speikii* and Red River Hogs (F. Magliocca pers. comm.).

Reproduction and Population Structure In Virunga N. P. and in neighbouring areas, mating takes place all year round, with a peak in Feb–Mar and Aug–Sep, at the start of the wet seasons. Births occur mainly in Jul–Aug and Jan–Feb when optimal grazing is available for lactating ♀♀ and growing piglets. Weaning occurs after 8–10 weeks. Litters of up to six piglets (average = 2.5 in Virunga N. P.) are born after a gestation period estimated at 18 (Asdell 1946, K. Viehl pers. comm.) to 21.5 weeks (d'Huart 1978). Litters of less

than four piglets account for 96% of field records, but as many as 11 offspring are known (Prickett, in Kingdon 1979).

Body growth is relatively rapid; adult size as well as sexual maturity are reached by both ♂♂ and ♀♀ at 18 months. No variation in female reproductive potential has been detected, and a yearly proportion of 46% of ♀♀ produce young. In the Virunga N. P. population, a reproductive potential of 113.6 young for 100 adult ♀♀ has been calculated. Net reproduction ratio suggests that each ♀ is replaced by 1.3 ♀♀, showing an increasing population in that area during the period of observation (d'Huart 1978).

In Queen Elizabeth N. P., the killing of piglets by newly arrived dominant ♂♂ seems to be sufficiently common to represent a major constraint on group dynamics, with up to 100% mortality in the litters of ♀♀ living with a newly established ♂ (Klingel *et al.* 2001). Although such incidents can be reliably inferred, it is rare for them to be observed directly so that the overall fertility of ♀♀ at parturition has probably been substantially underestimated.

Recorded sex ratios fluctuate between 1 : 1 and 1 : 2. The age ratio of the Virunga N. P. population is 67% adult (>18 months), 15% subadult (6–18 months) and 18% young. Seasonal changes in population structure are detected after the peaks of birth seasons. A mortality rate of 50–60% of piglets is estimated during the first year. It is mainly attributed to predation, but can also be due to weaning stress or to crushing by the mother. Additional mortality factors at adult age include fighting (♂♂), poaching, predation, parasitism and disease. Life tables suggest an average life expectancy of 3.5 years and an average life-span of five years, with a maximum of 18 years (d'Huart 1978).

Predators, Parasites and Diseases Major predators include Spotted Hyenas, Leopards and Lions. Large eagles prey on young piglets in savanna habitats. The high density of Lions in Aberdares N. P. would seem to have been the principal cause of a drastic Forest Hog population decrease since the late 1980s (Klingel & Klingel 2004b, R. Kock pers. comm.). Inversely, the expansion of the Forest Hog population in Queen Elizabeth N. P. is attributed to a temporary collapse of the Lion population combined with several years of high rainfall (H. Klingel pers. comm.).

Forest Hogs are hosts to a large number of ectoparasites, and a list of 11 species of ixodid ticks has been reported (d'Huart 1973). They are reportedly susceptible to rinderpest and populations have been greatly depleted by waves of rinderpest epidemics. Forest Hogs are also known to be a reservoir for African swine fever and trypanosomiasis, but their impact on the species is currently unknown.

Periodic toxicity in food plants (notably *Mimulopsis*) has been invoked for die-offs of Forest Hogs in the Mau forest, Kenya (Simon 1962).

Conservation IUCN Category: Least Concern. CITES: Not Listed.

The status of all West African Forest Hog populations is cause for concern, particularly given the high rates of forest loss and fragmentation in the region. Elsewhere, Forest Hogs are very vulnerable because widespread deforestation and illegal hunting for local consumption and a rapidly expanding bushmeat trade has led to declining numbers, and rapid fragmentation of subpopulations. In some areas of the Congo Basin, Forest Hogs are avoided by shotgun hunters because their flesh is considered to have an unpleasant taste, but this is by no means a widespread aversion nor is the taint widely recognized.

Hogs fall victim to snares and the meat is smoked to conceal its origin and sent to urban markets (R. Ruggiero pers. comm.).

Protected areas known to have important populations of Forest Hogs include: Sapo N. P. (Liberia); National Park of Upper Niger (Guinea); Taï N. P. (Côte d'Ivoire); Bia N. P. (Ghana); Odzala N. P. (Congo); Minkebe N. P. (Gabon); the Sangha Tri-National complex (Central African Republic, Congo, Cameroon), where large groups graze the bais; Maiko N. P., Virunga N. P. and Kahuzi-Biega N. P. (DR Congo); Rwenzori Mountains N. P. and Queen Elizabeth N. P. (Uganda); Aberdares N. P. and Mt Kenya N. P. (Kenya); and Bale Mountains N. P. (Ethiopia). During the 1940s, an exceptionally high concentration of Forest Hogs was reported to have developed in the area of Rutshuru (near Virunga N. P., DR Congo). A special hunting operation around Rutshuru was organized in 1945/1946 to reduce the populations of wild pigs, which were judged responsible for crop damage; some 77 Common Warthogs, 329 Bushpigs and 619 Forest Hogs were destroyed (Hoier 1952).

Both conservation (through captive breeding) and an obvious potential for domestication have been constrained by veterinary regulations designed to protect domestic pigs from any possible source of swine fever. This has led to extensive, but not always wholly rational, international bans on the import and export of wild pig species. The potential contribution of this grazing pig to protein

needs in Africa, under total or partial domestication, continues to be ignored in spite of increasing international calls to alleviate poverty.

Measurements

Hylochoerus meinertzhageni

HB (♂ ♂): 1374 (870–1900) mm, n = 7

HB (♀ ♀): 1172 (588–1780) mm, n = 6

T (♂ ♂): 318 (230–360) mm, n = 6

T (♀ ♀): 282 (105–380) mm, n = 5

HF c.u. (♂ ♂): 905 (790–1100) mm, n = 12

HF c.u. (♀ ♀): 828 (762–1000) mm, n = 10

E: n.d.

WT (♂ ♂): 177.4 (139.0–220.0) kg, n = 9

WT (♀ ♀): 150.6 (130.0–204.0) kg, n = 3

d'Huart (1978)

The longest tusk on record, measured from the base of the extracted tusk along the outer curve to the tip, from Semliki Forest, Uganda, measured 394 mm (Rowland Ward)

Tribe PHACOCHOERINI

Warthogs

Phacochoerini Gray, 1868. Proc. Zool. Soc. Lond. 1868: 47.

The warthogs may be readily separated from the rest of the extant suids on the basis of their complex, elongated and very high-crowned third molars – often the only cheektooth retained in mature and elderly individuals. Hypsodonty has been selected as an adaptive response to the consumption of more fibrous or abrasive plants in progressively more open and arid-adapted types of vegetation. Hypsodont grazing suoids were thought to be absent in western Eurasia, but Pickford (1988) recognized a suine tribe Hippohyini to accommodate the hypsodont Miocene genera *Hippohyus* and *Sivahyus* from the Siwalik Hills of the Indian sub-continent.

In Africa, three lineages of suids – the tetraconodont *Sivachoerus*–*Notochoerus* lineage plus species of the suines *Metridiochoerus* and *Kolpochoerus* – all displayed increase in size, height and complexity of the third molars through time, making them useful for biostratigraphic correlation (Cooke & Maglio 1972, White & Harris 1977, Cooke 1978a, Harris & White 1979). Kullmer (1999) compared the molar morphology of Plio-Pleistocene African suids with that of their extant counterparts and correlated increases in hypsodonty, length and complexity with adaptation to more open habitat and acquisition of a grazing diet. Harris & Cerling (2002) found, on the basis of stable carbon isotopes, that such a transition occurred during the Pliocene in the *Sivachoerus*–*Notochoerus* lineage, but that the earliest African representatives of the suines *Kolpochoerus* and *Metridiochoerus* were already well-established grazers. The diminutive *Metridiochoerus modestus* had a cranium that was very similar to that of *Phacochoerus*, but its teeth still retained the Y-shaped pillars that distinguish *Metridiochoerus* teeth from those of *Phacochoerus*.

Sectioned Common Warthog *Phacochoerus africanus* skull (old male) illustrating final position of third molars in maturity.

Contemporary warthogs are relatively small animals that probably derive from a still smaller immediate ancestor. However, some fossil Phacochoerini from the Plio-Plietocene were as large as small rhinoceroses, an enlargement possibly selected for as these pigs moved out into more exposed habitats.

John M. Harris

GENUS *Phacochoerus*

Warthogs

Phacochoerus F. Cuvier, 1826. Dict. Sci. Nat. 39: 383.

Frontal views of: left, Common Warthog *Phacochoerus africanus* and right, Desert Warthog *Phacochoerus aethiopicus*.

Juvenile Common Warthog *Phacochoerus africanus* showing succession and migration of teeth indicated by arrows (from Kingdon 1979).

Phacochoerus includes two extant species, the Common Warthog *Phacochoerus africanus* and Desert Warthog, *P. aethiopicus*. Two species of warthog have long been recognized by palaeontologists (Van Hoepen & Van Hoepen 1932, Ewer 1956, 1957, 1958, Cooke & Wilkinson 1978); Cuvier (1817) also considered them different species, as did Cumming (1970). However, Lydekker (1915) placed all warthogs in one species and, subsequently, during most of the twentieth century, the Common Warthog has been incorrectly referred to as *P. aethiopicus*. The confusion has only recently been clarified with the discovery of an extant subspecies of the extinct Cape Warthog in Somalia, namely, the Desert Warthog (*P. aethiopicus somaliensis*) (Grubb 1993b, d'Huart & Grubb 2001). Divergence in mitochondrial and single-copy nuclear DNA sequences suggests differentiation as far back as the late Pliocene (Randi *et al.* 2002). The two species are distributed throughout wooded or open country of sub-Saharan Africa, and were present in North Africa during the upper Pleistocene. They are now absent from much of southern Africa, where their former extent of range is not well known. A comprehensive review of warthog systematics is provided by Grubb & d'Huart (2010).

Both species are diurnal graminivorous pigs, relatively hairless, with a sparse pelage of coarse bristles not concealing the body outline. 'Whiskers' of long white hair are present along the lower jaw, white hairs in the ears, and there is a long, thick dorsal mane starting between the ears and ending at the base of the tail. The legs are densely haired except for the carpal callus, and there is a terminal tail tuft. The characteristic physiognomy includes a broad snout, enormous canine tusks curving upward as well as laterally, facial warts, and orbits elevated and placed far back; hence, the eyes are at the top of the head providing a clearer and more extensive field of view especially when feeding. There are distinctive warts on the cheeks and just below the eyes, which are better developed in ♂♂, and contribute to absorbing blows and cushioning the skull during combat. Legs are slender, relatively longer than in other genera; hooves relatively narrow.

The skull in warthogs is transformed by adaptations for graminivory, and so differs strongly from that of members of the genera *Sus* or *Potamochoerus*. The lateral outline is wedge-shaped, slanted backward due to the downward flexure of the facial part in relation to the neurocranium. Zygomatic arches are very broad. The snout is much shortened in front of the tusks, not elongated and vertical-sided as in *Potamochoerus* because digging is of reduced importance. The condyle (on the long ascending ramus of the dentary) and glenoid lie well above the level of the toothrow, facilitating crushing or shearing of forage. The ascending ramus of the dentary slopes backward. The superficial masseter closes the jaw and pulls it laterally, producing a shearing action. Raising of the jaw joint is accompanied by a deepening of the maxilla, accommodating the hypsodont cheekteeth. The extreme anteroposterior compression of the postorbital region reflects the reduction of the temporalis muscle, a rapid masticatory action not being required for plucking grass. Paraoccipital processes are lengthened allowing the digastric muscle to act as a jaw opener, even though the neurocranium is raised above the dental arcade.

The adult dental formula is $I^{0-1/0-3}, C^{1/1}, P^{3/2}, M^{3/3} = 26-34$. Only the first upper incisors alone are (variably) retained. Lower incisors lie in a shelf-like projection of the dentary, or are impacted, not erupting above the gum. The tubular upper tusk sockets are directed forward and outward; the upper tusks are large, curling outward and backward above the level of the snout, and are not abraded at the tips by wear with the lower tusks, which are compressed, wearing against the anterior face of the uppers. The tusks of ♀♀ are relatively large compared with other genera. Premolars are reduced and together with the anterior molars, commonly shed in adulthood. Molars are hypsodont, and formed of well-cemented, closely packed, little-folded, oval to sub-triangular enamel columns; the third molar is considerably elongated by a large talon (heel).

Peter Grubb

Phacochoerus aethiopicus DESERT WARTHOG

Fr. Phacochère du désert; Ger. Wüstenwarzenschwein

Phacochoerus aethiopicus (Pallas, 1766). Misc. Zool. p. 16. 'Promontoria Bona Spei advectus'; between Kaffraria and Great Namaqualand (South Africa, Eastern Cape Prov.), two hundred leagues from the Cape of Good Hope according to Vosmaer (1766).

ABOVE: Desert Warthog *Phacochoerus aethiopicus*.

RIGHT: *Phacochoerus* spp. Outlines of rhinarium (snout) and underlying nasals and mandibular occlusion in: above, Common Warthog *P. africanus*; below, Desert Warthog *P. aethiopicus*.

Taxonomy The Desert Warthog was the first species in the genus to be scientifically described and illustrated. Knowledge of this species was eventually eclipsed by the volume of information gleaned from the related Common Warthog *Phacochoerus africanus* in terms of numbers of museum specimens collected, extent of field studies, and published photographs, so diagnostic characters have been neglected (Grubb & d'Huart 2010).

Polytypic, with two nominal subspecies, one extinct since about 1871. An East African population (*delamerei*) was named by Lönnberg (1909), who recognized its resemblance to the South African animal. Lydekker (1915) placed all warthogs in one species and has been followed by most authors in the twentieth century, though palaeontologists were aware that there were two species (Van Hoepen & Van Hoepen 1932, Ewer 1957, Cooke & Wilkinson 1978). Reappraisal of the status of *P. aethiopicus* (Grubb 1993b) has been followed by a study of its distribution in relation to *P. africanus* in the Horn of Africa (d'Huart & Grubb 2001), discovery of considerable genetic divergence from the latter species (Randi *et al.* 2002), and morphological differences between both species (d'Huart & Grubb 2005). See Grubb & d'Huart (2010) for a detailed review of the 'rediscovery' of the species. Synonyms: *angalla*, *delamerei*, *edentatus*, *pallasii*, *typicus*. Chromosome number: not known, but probably $2n = 34$ as in *P. africanus*.

Description Very poorly known species in spite of being relatively abundant in East Africa. South African animals are known from two illustrations indicating a small-eared animal with dark face and snout over a light cheek and lower jaw, and a swelling round the eye, below which is a drooping blunt wart. Skull similar in proportions to that of the Common Warthog, but diagnostically distinguished by other cranial and dental characters. The upper incisors are always absent (d'Huart &

Grubb 2001). Lower incisors are absent or reduced to four or less, very small, hardly protruding from alveoli and probably always concealed by gums. Lower and upper canines are less curved than in *P. africanus*, the wear facet on the lower canine is differently placed, and the lower canines are less compressed (Ewer 1957). The third molars are also different: when all the enamel columns have come into wear, no roots have yet formed, unlike the condition in *P. africanus*. At this stage, all the columns are of about the same length and are able to continue growing, extending the life of the tooth (Van Hoepen & Van Hoepen 1932, Ewer 1957, Cooke & Wilkinson 1978). Sphenoidal pits in the neurocranium floor on each side of the vomer are enormously enlarged and opened out, occupying the whole area between internal nares and basioccipital and basisphenoid, deepening the vomerine ridge; they are separated from the auditory bullae only by a thin wall of bone. Zygomatic arches are robust with large sinuses forming a spherical inflation of the jugal (malar) just in front of its articulation with the squamosal (temporal) (De Beaux 1922, Ewer 1957). A fine ridge runs down the front of the skull from the orbital rim across the lachrymal and maxilla, and while not necessarily diagnostic, characterizes many skulls of this species (d'Huart & Grubb 2001). In the few available samples, skull lengths for the two sexes do not overlap, suggesting perhaps greater sexual dimorphism than in the Common Warthog.

Geographic Variation

P. a. aethiopicus (Cape Warthog): formerly southern part of the species' distribution. Known from two illustrations (eighteenth and nineteenth century). Aart Schouman's painting of the lectotype (Tuijn & Van der Feen 1969) shows a stout animal with relatively small ears, dependent, blunt suborbital warts, and contrasting colouration between a dark face and snout and light cheek and

Lateral and frontal views of skull of Desert Warthog *Phacochoerus aethiopicus*.

Phacochoerus aethiopicus

lower jaw. External differences between a boar in the menagerie of the Zoological Society of London and a Common Warthog from Eritrea were described as ‘very obvious’ (Sclater 1869): flanks less naked, hairs on the back and nape of the head less thick and shorter; ears shorter, less pointed and less naked, densely coated with hair; and whiskers less developed. The illustration of the head shows a swelling round the eye and a broad, drooping suborbital wart with a blunt end.

P. a. delamerei (Lord Delamere’s or Somali Warthog): northern part of the species’ distribution. Suborbital warts in adult ♂♂ of a characteristic shape – curled or bent down at the tip. Skulls from N Somalia are smaller than those from S Somalia and Kenya, but sample sizes are very small. Recorded as having a blond dorsal mane in Somalia. Characters of canines and third molars recorded in *P. a. aethiopicus* not yet studied in this subspecies. Other dental and cranial characters identical with those of the nominate subspecies. Genal warts in adult ♂♂ unlike those known from *P. a. aethiopicus*, characteristically shaped, curled or bent down at the tip though with much variation in volume, form and orientation. Tips of ears bent backwards, appearing to have rounded or blunt tips and an angular contour. Suborbital region swollen, forming pouches that often extend to the base of the genal warts, resembling those known from *P. a. aethiopicus*. The comparatively broader skull and its shorter basioccipital region give the impression that the head is more egg-shaped than diabolo-shaped (d’Huart & Grubb 2005).

Similar Species

Phacochoerus africanus. Largely allopatric, but recorded in sympatry in Tsavo West and Tsavo East N. P. (Culverwell *et al.* 2008). There is also a population occupying an enclave within the range of *P. aethiopicus* in N Somalia (d’Huart & Grubb 2001). Attain larger size, at least in some populations, with skull length up to 466 mm in ♂♂ and up to 409 mm in ♀♀; they possess functional incisors and very small sphenoidal pits; lack thickening of zygoma; canines

reported to be more curved and third molars less specialized; genal warts cone-shaped and usually not with bent or curled tips; ears leaf-shaped, with pointed tips and a sinuous contour; suborbital areas without a pronounced swelling; head looks more diabolo-shaped (differences illustrated in d’Huart & Grubb 2005). Occupy a much wider range of habitats.

Distribution Endemic to Africa. A polytypic species occurring in the Somali–Masai Bushland BZ and formerly in part of the South–West Arid BZ, but not in intervening areas.

Historical Distribution Formerly South Africa, in the south-eastern parts of former Cape Province and apparently adjacent parts of KwaZulu–Natal. Early records of wild pigs do not usually discriminate between Bushpig *Potamochoerus larvatus* and warthogs and the two species of warthogs were not distinguished in the field. There are no records of warthogs from most of the Western Cape and Northern Cape. The Desert Warthog is known by reliably identified specimens from only the following localities: the type locality; between the Sondags and Boesmans Rivers in Eastern Cape; the upper Orange R., Northern Cape; and KwaZulu–Natal (Grubb & d’Huart 2010). It is not known whether the distributions of the two species overlapped or whether they were strictly allopatric, although the Desert Warthog ranged north into the former Transvaal in the late Pleistocene (Ewer 1957).

Current Distribution Distribution in East Africa does not seem to have changed significantly even in recent times, and they remain known only from E Ethiopia and Somalia, and in Kenya mostly north of the Ewaso Ngiro R. The range has been found to extend southwards to Tsavo West and East National Parks (west of Athi River and south of the Galana R.; Culverwell *et al.* 2008, de Jong *et al.* 2009).

Habitat The Desert Warthog is a species of open arid regions. The South African population occurred in the Karoo but there is no

information on habitat preferences and habitat use. Its distribution may have been limited by winter temperatures. The range of the northern population lies within the Somalia–Masai Bushland BZ, with vegetation of ‘Somalia–Masai *Acacia–Commiphora* deciduous bushland and thicket’ and ‘Somalia–Masai semi-desert grassland and shrubland’. These vegetation types range from xerophyllous bush and open woodland to sub-desert steppe. Dominant grasses are *Chrysopogon* species in more arid areas and *Chloris* species in semi-arid habitats. Desert Warthogs prefer plains on predominantly sandy soils, and avoid hilly terrain. Most records are from lowland areas below 200 m, a few are at higher altitudes, but none is above 1400 m. Desert Warthogs are dependent on occurrence of water and shade and occupy regions with rainfall of 100–600 mm per annum. Areas with higher rainfall, which correspond to the zone above the 1000 m contour, are avoided, as are the driest, hottest and most desertic regions with rainfall less than 100 mm per annum, corresponding with the hot coastal zone of Somalia between 12 and 9° N, and extending to the eastern tip of Ogaden.

Abundance The Desert Warthog was one of the most widespread and common game animals in Somalia, at least in the 1960s. Ground and aerial surveys in the Nugaal valley, Somalia, as well as an aerial survey between Garowe and Ras Hafun in 1989, confirmed that warthogs are locally abundant (P. Moehlman pers. comm.). Similarly, field observers reported that warthogs were very abundant in 1996 in Mahadday and Jowhar Districts of Middle Shebelle (A. Massarelli pers. comm.). In Ethiopia, they are common in the whole Ogaden region and can be observed both in family sounders in bushy areas and in larger aggregations of up to 30 individuals around permanent wells and close to towns (Wilhelmi *et al.* 2004). In Kenya, they were reported to be abundant near water-points in Garissa District, Kenya, in 1999 and 2004 (T. Butynski & A. Caron pers. comm.), common on the Laikipia Plateau and in the Samburu/Buffalo Springs/Shaba National Reserves area, but rarer towards Maralal and Marsabit in 2000 (S. Williams pers. comm.).

Adaptations Morphologically, the Desert Warthog is the most specialized living suid, but nothing is known of its habits and physiology. As incisors are functionally absent, lips and gums are used to detach or pick up food items. Rootless third molars suggest adaptation to a more abrasive diet. The specialized condition of the zygoma and differences in wart shape suggest the style of combat between ♂♂ is different from that of the Common Warthog.

Foraging and Food The potentially longer-lived and rootless third molar and absence of functional incisors imply significant differences in diet and feeding techniques from the Common Warthog. These await investigation.

Social and Reproductive Behaviour Physiological adaptation to drier, and perhaps, colder environments than the Common Warthog probably influence, say, their use of shelters and adaptation to watering regime. These, in turn, are likely to be correlated with currently unknown differences in social structure.

Reproduction and Population Structure There is currently no information available for the species.

Predators, Parasites and Diseases Likely predators include Lions *Panthera leo*, Leopards *P. pardus* and hyaenas. Extinction of the South African population may have been hastened by rinderpest.

Conservation IUCN Category: Least Concern. CITES: Not listed.

The Desert Warthog is known to exist in Samburu, Buffalo Springs, Shaba and Doodor National Reserves, and in Tsavo West and East National Parks, Kenya. From the distribution of reliably identified specimens, it will probably be found in Malkamari N. P. and Losai, Marsabit, Arawale and Boni National Reserves of Kenya, and Lag Badana/Bushbush N. P. in Somalia. In Ethiopia, Desert Warthogs are likely to occur in Babile and Yabelo Wildlife Sanctuaries and associated Controlled Hunting Areas (the Lower Wabe Shebelle and Borana, respectively) in Ethiopia (d’Huart & Grubb 2001, Culverwell *et al.* 2008). Although the species is widespread in the Ogaden, there is a concern that hunting for bushmeat trade may become a threat (Wilhelmi *et al.* 2004).

Measurements

Phacochoerus aethiopicus

Skull measurements:

P. a. aethiopicus

GLS (♂♂): 378.0 (366–393) mm, n = 4

GLS (♀♀): 330, 352 mm, n = 2

GWS (♂♂): 224.2 (220–230) mm, n = 3

GWS (♀♀): 179 mm, n = 1

South Africa

P. a. delamerei

GLS (♂♂): 393.0 (369–407) mm, n = 6

GLS (♀♀): 328.7 (325–331) mm, n = 3

GWS (♂♂): 228.3 (209–245) mm, n = 6

GWS (♀♀): 182.0 (169–197) mm, n = 3

Kenya and S Somalia (Jubaland)

GLS (♂♂): 357.0 (348–364) mm, n = 5

GLS (♀♀): 301 mm, n = 1

GWS (♂♂): 202.0 (192–227) mm, n = 5

GWS (♀♀): 167 mm, n = 1

N Somalia

Museum specimens (BMNH, NMK, PCM) and from literature; a single specimen in the AMNH from Galma Galla, Garissa District, Kenya, had the following measurements: TL: 1755 mm; T: 440 mm; HF c.u.: 275 mm; E: 142 mm (T. Butynski pers. comm.)

The record tusk length (measured along the outer curve from the base to the tip) is unclear due to lack of distinction between the two warthog species in most record books (see Butynski & de Jong 2010)

Phacochoerus africanus COMMON WARTHOG

Fr. Phacochère; Ger. Warzenschwein

Phacochoerus africanus (Gmelin, 1788). Syst. Nat., 13th edn, 1: 220. 'Habitat in Africa a capite viridi ad caput bonae spei'; restricted to Senegal, 'Cape Verd [Verdel]' (Lydekker 1915: 373).

Common Warthog *Phacochoerus africanus*.

Taxonomy The Common Warthog is here treated as a species distinct from the Desert Warthog *P. aethiopicus* (Ewer 1957, Cooke & Wilkinson 1978, Grubb 1993b, 2005). Four geographical variants of *P. africanus* were provisionally recognized by Grubb (1993b) largely on the basis of skull size and proportions indicating a clinal species. Muwanika *et al.* (2003) investigated patterns of genetic variation in 181 specimens from 24 localities in Africa. They identified 70 mitochondrial haplotypes that clustered into three well-defined clades representing individuals from western, eastern and southern Africa. They concluded that differentiation at both mitochondrial and nuclear loci supported the existence of three lineages that resulted from Pleistocene climatic fluctuations. Synonyms: *aeliani*, *barbatus*, *barkeri*, *bufo*, *centralis*, *fossor*, *haroia*, *incisivus*, *massaicus*, *sclateri*, *shortridgei*, *sundevallii*. Chromosome number: $2n = 34$ (Bosma 1978); the chromosome complement consists of 14 pairs of (sub)metacentric autosomes and two pairs of acrocentric autosomes (Musilova *et al.* 2010).

Description At first glance an adult Common Warthog jauntily trotting across an open savanna with its tail and mane erect and large head held high resembles a miniature rhinoceros rather than a typical pig. The head is unusually large, the forehead, muzzle and snout broad and flattened, with the eyes placed high and wide. Ears are prominent and broad rather than pointed, and can protrude well above the level of the head. Warts, from which the animal derives its name, are formed of tough fibrous tissue and comprise the

infraorbital warts attached to the zygoma, mandibular warts along the angle of the lower jaw, and, in ♂♂, supraoral warts situated on the snout behind the tusks. A dense, side-burn-like cover of long white bristles generally obscures the elongated mandibular wart. The neck is short and the nape, withers and back carry a mane of long black and brown bristles. The mane can be erected in displays associated with fight/flight situations. The Common Warthog's dark grey, almost black colour is determined by its skin colour rather than by its sparse coat. The skin is sparsely covered with white bristles and can take on differing hues of grey or brown depending on the colour of the soil in its holes or wallows. The tail is long and slender with a flattened end carrying bristles. The legs are proportionately longer than in other suids and knees bear characteristic callosities that are present even in the foetus. The hooves are narrower than those of the Bushpig *Potamochoerus larvatus*. Both the preorbital area and the lip carry dermal secretory glands (Estes *et al.* 1982). Tusks and warts are markedly larger in ♂♂ and ♀♀ have one pair inguinal and one pair abdominal nipples.

The skull slopes sharply forward from the braincase to the nostrils, and the rostrum is considerably elongated. The orbits are small, and there are distinct supraorbital ridges on the inner sides. The supraoccipital crest is well developed, lying at an angle backwards of the braincase, thereby leaving a wide area at the back for the attachment of the massive neck muscles. The paraoccipital processes are long, extending nearly to the level of the bottom of the angle of the mandible (Skinner & Chimimba 2005). The blunt upper

Lateral, palatal, dorsal and frontal views of skull of Common Warthog *Phacochoerus africanus*.

canines, or tusks, flare upwards from the snout and in older animals, particularly ♀♀, curve inwards. The lower canine is triangular in profile, scimitar-like and is sharpened against the lower edge of the upper canine. Unlike the upper canine, its dentine core is covered by enamel. The key dental features distinguishing this species from the Desert Warthog are the presence of one pair of upper incisors and two to three pairs of lower incisors. Upper incisors are absent in Desert Warthogs and lower incisors, if present at all, are rudimentary (Grubb 1993b). The adult upper and lower incisors of the Common Warthog also have deep roots and prominent crowns, which converge and make contact. The structure of the third molar also differs between the species. In *P. africanus* roots are formed in the anterior molar columns before all the cusps have come into

wear while in the extinct Cape Warthog *P. aethiopicus aethiopicus* and presumably also in *P. a. delamerei* roots are formed only once all of the columns have erupted and are in wear (Shaw 1939, Cooke 1949, Grubb 1993b). Unlike any other African suids, the roof of the skull of *P. africanus* shows two deep sphenoidal pits behind the internal nares region (Grubb 1993b).

Geographic Variation

P. africanus africanus: Mauritania eastwards to S Ethiopia.

P. a. aeliani: confined to Eritrea, N Djibouti and Somalia.

P. a. massaicus: eastern and central Africa, in Zambia, Malawi, N Mozambique, Tanzania and S Kenya.

P. a. sundevallii: SW Angola, N Namibia, Botswana, Zimbabwe, S Mozambique and parts of South Africa.

Similar Species

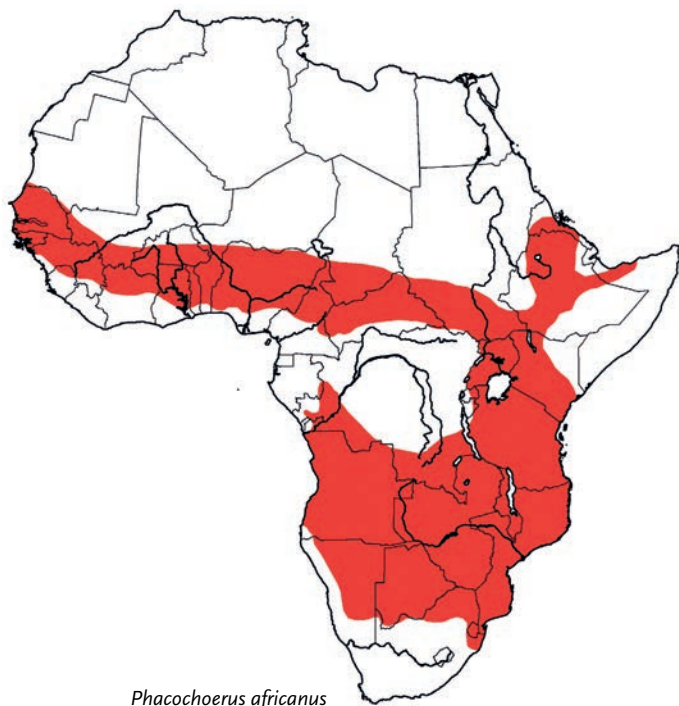

Phacochoerus aethiopicus. Only recently distinguished as a living separate species based on cranial features and molecular evidence (Grubb 1993b, Randi *et al.* 2002; and see Grubb & d'Huart 2010). A supposedly consistent distinguishing feature in the field is the shape of the infraorbital warts in ♂♂: in the Desert Warthog they have a distinct anterior bend, whereas in the Common Warthog these generally point directly outwards (see also species profile for *Phacochoerus aethiopicus*). The differences between the two species are illustrated by d'Huart & Grubb (2005). Largely allopatric, but recently recorded in sympatry in Tsavo West N. P. (Culverwell *et al.* 2008).

Potamochoerus larvatus. Also occurs in moister savanna habitats, but readily distinguished from warthogs in the field by its distinctly shaggy, reddish-brown coat, rounded back, pointed pixie ears, low slung head, more pointed snout without upturned prominent tusks or warts, and its loping gait. Unlike warthogs, the tail is never held erect while running.

The more brightly coloured Red River Hog *Potamochoerus porcus* and the much larger Forest Hog *Hylochoerus meinertzhageni*, which has a well-developed black shaggy coat, occur in forests and their ranges have only marginal overlaps with the Common Warthog.

Distribution Endemic to Africa. Their former distribution extended across the West African Guinea Savannah and Sahelian zone from Senegal, Gambia and extreme S Mauritania eastwards to Sudan, Ethiopia and Djibouti and from there southwards through East Africa to the savannas of southern Africa. The Tugela R. marks their former southerly limit of distribution in KwaZulu–Natal (Rowe-Rowe 1994). Historically, the Common Warthog did not occur in the arid Karoo of South Africa, where it was replaced by the extinct Cape Warthog *P. aethiopicus aethiopicus*.

Today, the Common Warthog remains widespread in sub-Saharan Africa, being found in scattered populations in West Africa eastwards to Ethiopia and then southwards in protected areas and unsettled, or very lightly settled, areas in East and south-central and southern Africa. The continuous expansion of the Sahel-zone has resulted in a marked contraction in the species' former range in the north since the early 1980s, and accounts for its probable extinction in Niger (J. Newby, in Vercammen and Mason 1993) although it is possible they may still persist in the south-central Air Mts (J. Newby pers. comm.).

Common Warthogs are still recorded in the savanna woodlands of SW Mali (Chardonnet 2001a). They have been reintroduced to some parts of their former range in southern Africa (e.g. in Swaziland, where the indigenous population went extinct), and introduced elsewhere (e.g. in NE Algeria, as a result of an escaped captive population, and to the Eastern Cape Province of South Africa).

Habitat Confined to moist and dry African savanna grasslands, open bushlands and woodlands and usually within range of perennial surface water (although water is not considered to be an essential habitat requirement; Skinner & Chimimba 2005). Usually absent from forests, extensive thickets, cool montane grasslands and deserts and succulent steppes. However, the population in the Goda Mts in Djibouti mainly occupies forested areas (Künzel *et al.* 2000). Although typically associated with lowland savannas, they reach elevations of 3500 m in the Ethiopian Highlands (and large numbers survive in Bale Mountains N. P.; Yalden *et al.* 1996).

The need to sleep in holes in the ground at night links the distribution of this species to the formerly more widely distributed Aardvark *Orycteropus afer*, although in some parts of West Africa Bigourdan (1948) reported that Common Warthogs generally did not sleep in holes at night and only used Aardvark burrows as a last resort. They are capable of excavating their own holes and often modify existing holes extensively. Subterranean erosion gullies are also used and holes and gullies may be shared with porcupines that use them by day (Cumming 1975).

In a quantitative study of habitat selection, Cumming (1975) found the highest densities of Common Warthogs in drainage line grasslands on nutrient-rich soils and in *Acacia* savannas on alluvial terraces. These habitats supported highly palatable grasses, such as *Urochloa mossambicensis*, which were grazed during the wet season and other species, such as *Digitaria milanjiana*, which provided an abundant store of rhizomes that were rooted during the dry months. Lowest densities occurred in miombo woodland habitats and in *Combretum* and *Baikiaea* thickets and woodlands on deep sandy soils. Seasonal

shifts in habitat densities occurred as these animals changed from wet season to dry season feeding grounds within their home-ranges in the Sengwa area. Common Warthogs will congregate on the flush of green grass following dry season burns.

Abundance Seldom a dominant component, either numerically or in terms of biomass, within African large herbivore communities, although in some protected areas local densities may exceed 15–20 ind/km². More typically, densities range between 1 and 10/km² in protected areas, although local densities of 77/km² were found on short grass in Nakuru N. P. (Radke 1985, 1991a).

The overall number of Common Warthogs in southern Africa (Angola, Zambia, Tanzania and southwards) has been estimated at about 250,000 (Cumming 1999). Estimates for the numbers of Common Warthogs in West and north-central Africa are not available although they occur in most protected areas in the savannas. Populations in Benin, Central African Republic and N DR Congo were greatly reduced by rinderpest during the 1980s (Vercammen & Mason 1993). Populations are susceptible to droughts and resulting population crashes have been reported in several parts of Africa (e.g. Mason 1990a). However, the potentially high reproductive rate of Common Warthogs does allow for rapid recovery when conditions improve.

Adaptations Differs from other suids in several important respects and these differences emphasize that Common Warthogs are suids beautifully adapted to dry savannas and steppes. The unusually large head, with eyes set high and wide, provides a wider field of vision than other suids. The snout and teeth are adapted to grazing and to rooting hard ground while the warts and tusks reflect displays and fighting style. Their gait, with head held high, is more akin to that of an antelope than the pigs.

Common Warthogs are the smallest of the diurnal bare-skinned large mammals and, unlike any other ungulate, sleep in holes at night. The subcutaneous fat layer is very thin, if present at all, and, in contrast to other suids, they are markedly thermolabile and their daily range in body temperature can vary by as much as 7 °C (Cumming 1975). Piglets are unable to maintain their body temperature without huddling and access to shelter (Sowls & Phelps 1966) and even at one year old they will die if exposed to early morning temperatures of around 1 °C if denied access to holes (Cumming 1975). In winter, overnight and early morning temperatures approaching zero are common in arid savannas while the temperatures in occupied holes at that time of year are considerably higher (Cumming 1975). Daily temperature was close to 20 °C within Common Warthog holes in the Masai Mara National Reserve and Nakuru N. P. and temperature fluctuations within holes were markedly lower than fluctuations in temperatures outside the hole (Radke 1991b). Geigy (1955) found a temperature of 30 °C and relative humidity of 90% in a burrow close to Mofu in Tanzania. It thus seems probable that the cluster of features involving bare skin, absence of a subcutaneous fat layer, thermolability and sleeping in holes may reflect adaptations to conserving energy and water in arid habitats. Clearly, these adaptations may not be crucial in hotter, more humid areas. Physiological studies to test such a hypothesis have yet to be undertaken.

Ewer (1957) characterized Common Warthogs as highly specialized 'grass pluckers' on the basis of the structure and wear on the incisors and her observations of them grazing short grass 'lawns' in

Common Warthog *Phacochoerus africanus* juvenile.Common Warthog *Phacochoerus africanus* juvenile myology.

KwaZulu–Natal. Their specialized bunodont molars are unlike those of other suids and with their flattened, grinding surfaces are adapted to a graminivorous diet (Ewer 1958). The variable number of incisors (Child *et al.* 1965) suggests that they may be dispensable and that Common Warthogs may use their lips, as do hippos, to graze. Watching the animals graze on short grass from a distance of a few centimetres has not clarified the question (D. Cumming pers. obs.). Common Warthogs change their diet seasonally and this is evident in the structure of the snout and the rhinarium. The dorsal edge of the rhinarium is relatively sharp, tough and firmly anchored to the nasals to allow them to scoop shallow depressions in hard, dry earth to unearth rhizomes – a feat that the Bushpig, with its more bulbous and flexible rhinarium, is incapable of performing (Cumming 1975). Common Warthogs are also capable of grazing efficiently on taller swards during the rains and of using their tusks to shred grass seeds when these ripen towards the end of the rains. The grinding surface of the molars is unlike that of other suids and is adapted to a highly lignified diet of grass leaves and rhizomes. The oft-repeated tale that Common Warthogs use their tusks to dig holes and root for rhizomes and tubers is untrue. The development of callosities on the fore-carpals on which they ‘kneel’ is clearly linked to grazing short grass and rooting for rhizomes. The callosities, absent in other suids, are evident in the embryo. A tame Bushpig that grew up with two Common Warthogs was occasionally seen trying to kneel in the same manner as the Common Warthogs, but once in this position it was clearly perplexed about what to do next and neither rooted nor grazed and soon stood up.

Marked sexual dimorphism in the size of upper canines, or tusks, signifies their role in displays and inter-male rivalry. Linked to this is the sexual dimorphism of the supraoral and particularly the infraorbital warts. While the tusks may serve a similar function to horns in antelope, the three sets of warts (infraorbital, supraoral and mandibular) are situated so as to protect the eyes and underlying bones, tendons and muscles that are intimately associated with feeding.

Warthogs are diurnal and generally emerge from burrows in the morning at about sunrise and retire at dusk. Feeding generally takes place during the cooler periods of the day in the morning and late afternoon with the mid-day period spent resting in the shade or basking out in the open if it is cool. In general, about six hours a day

are spent feeding, two hours walking and 2–3 hours resting with less than an hour spent on other activities such as drinking, wallowing and social activities (Clough & Hassam 1970, Cumming 1975). The remaining time of roughly 12 hours is spent in holes. However, times spent on different activities vary seasonally and with the reproductive cycle. Pregnant ♀♀ will spend a greater proportion of time resting up in late pregnancy and mothers suckling young in burrows during the postnatal period may spend as little as two hours a day feeding (Cumming 1975). The frequency of drinking and wallowing is strongly temperature-dependent.

Foraging and Food Common Warthogs are almost entirely graminivorous, plucking green grass when this is available but also shredding grass seeds towards the end of the rains and rooting for grass rhizomes during the dry season (Cumming 1975). Reports from East Africa (e.g. Field 1970b, 1972) suggest that in some areas they may be predominantly grazers – a feature possibly linked to a dual wet season and availability of green grass through much of the year. In a recent study of the carbon and oxygen isotopes in the tissue of extant and fossil Suidae, Harris & Cerling (2002) characterize *Phacochoerus* as a hyper-grazer.

In southern Africa a single wet season and long dry season spanning 7–8 months leads to clear seasonal shifts in diet and mode of feeding. In the first and so far only quantitative year-round study of Common Warthog diet and feeding behaviour, Cumming (1975) found that Common Warthogs grazed on at least 34 species of grass during the rains. As seed ripened towards the end of the rains they spent more time stripping seeds from the inflorescences of species such as *Urochloa*. During the dry season they rooted for the rhizomes of *Digitaria milaniana* or *Tristachya superba* and occasionally *Oryza barthii* and *Phragmites* or the swollen leaf bases of *Setaria* species. Cumming (1975) reported 3–5 tons of rhizome (*D. milaniana* and *T. superba*) per hectare in favourable dry season habitat in the Sengwa area – enough to support ten Common Warthogs per ha for the six-month dry season. Observed density was 0.28 ind/ha in such habitat. The only other larger mammal found using this major food resource was the Cape Porcupine *Hystrix africaeaustralis*.

Common Warthogs are widely reported in the literature to eat fallen fruits, sedges, tubers and bulbs with the suggestion that the latter may

Common Warthog *Phacochoerus africanus*.

allow them to survive through droughts. At Sengwa fallen fruits formed only a very occasional dietary item and Common Warthogs were never recorded eating tubers and bulbs (i.e. underground storage organs of non-graminaceous plants) although Bushpigs, Chacma Baboons *Papio ursinus* and Cape Porcupines ate these. When offered ripe fallen *Acacia* pods, a favourite food item for many ungulates, tame Common Warthogs rejected them but a tame Bushpig readily ate them. Common Warthogs were regularly seen feeding on stomach and intestinal contents at predator kills in the Masai Mara National Reserve by Radke (1985) and have been recorded eating carrion elsewhere (Wilson 1975). They will, as many ungulates do, chew on old bones (osteophagia) and also exhibit geophagia and coprophagia (Cumming 1975, Mason 1982). The remains of a rodent were found in one of 600 faecal samples examined at Sengwa (Cumming 1975). Although not as large a problem as Bushpigs, Common Warthogs are sometimes a problem in agricultural lands, such as rice fields in Guinea-Bissau and peanut crops in E DR Congo (Vercammen & Mason 1993).

Social and Reproductive Behaviour Common Warthogs are social animals, with the matriarchal sounder (family group), usually comprising an adult ♀ with her immediate litter and sometimes one or two female offspring of previous litters, forming the core social unit. Young ♂♂ leave, or are evicted from, matriarchal sounders at the end of their first year and form bachelor groups with other yearlings or older animals. Adult ♂♂ are usually solitary or in fluid bachelor groups of 2–4 animals. Breeding ♀♀ leave their sounder to farrow alone in holes but they may be joined after a week or two by yearling or subadult female offspring of previous litters. Durable social bonds between sows and their offspring were recorded in the Sengwa area. Where two or more related sows have bred they may join to form larger sounders of 12–18 animals, but sounder size is ultimately limited by the size of the burrows in which they sleep at night (Cumming 1975). More recently both solitary and cooperative breeding strategies within the same Warthog population have been described and analysed in terms of evolutionary pressures acting on sociality in the species (White 2008, 2010, White *et al.* 2010, White & Cameron 2011a, b). As in the Sengwa population (Cumming 1975), Common Warthogs in the Hluhluwe-iMfolozi Park in KwaZulu-Natal, South Africa, were dispersed in clans (White & Cameron 2009).

Home-range areas vary with locality. Average home-range areas of 24 ha in the Eastern Cape, South Africa, 171 ha in Zimbabwe and up to 600 ha in East Africa have been recorded (Somers *et al.* 1994, Cumming 1975, Radke 1991a, respectively). Home-ranges overlap and there is no evidence of boundaries, core areas or sleeping holes within the home-range being defended. The focus of activity within the home-range may shift seasonally, or boundaries may be extended temporally, in response to changing availability of food and water. Occasional exploratory forays beyond home-range boundaries may occur and young animals may disperse several kilometres from their initial home-range. There is no evidence of large-scale seasonal movements of Common Warthogs despite their occurrence in arid zones. Reports of daily distance travelled vary from 6 km in Uganda (Clough & Hassam 1970), to 3.4 km for matriarchal sounders in Sengwa in Zimbabwe (D. Cumming pers. obs.) and 1.6 km in a nature reserve in the Eastern Cape (Somers *et al.* 1994). They change sleeping holes frequently and there are usually many more holes available than there are Common Warthogs (Radke 1991b).

In most parts of their range, and particularly in areas that experience a marked drop in temperature at night, Common Warthogs regularly enter holes at dusk and emerge at about sunrise with actual times of entry and emergence following the seasonal changes in day length (Cumming 1975). Holes may also be used as refuges from the rain. In the Sengwa area, few holes were used more than 70% of the time and animals frequently changed holes with the result that holes were used by more than one sounder. On occasion as many as 15 animals from related sounders, or members of larger filial groups, shared larger holes or burrows in erosion gulleys on the same night (Cumming 1975). On entering smaller and shorter Aardvark burrows, or holes that are being explored for the first time, Common Warthogs will generally approach the entrance, about turn and reverse into the hole (Geigy 1955, Frädrieh 1965).

Scent-marking begins in both sexes at 6–7 months of age (Cumming 1975) and is achieved by rubbing the damp patch in front of the eye (preorbital gland) or flange of the upper lip beside the tusks, on tree trunks, stumps and other solid objects. Adult boars will spray urine, and presumably secretions from the preputial gland, over the urine of ♀♀. Marking with preorbital and lip glands is carried out more frequently by ♂♂ and particularly during fighting and during the mating season, while ♀♀ mark the edges of their home-ranges more

Silhouette of Common Warthog *Phacochoerus africanus* in 'proud posture'.

frequently (Radke & Niemitz 1989). Allo-marking is uncommon (Somers *et al.* 1995). There is no evidence to suggest that Common Warthogs use dung piles in marking.

Intra-specific threat displays include standing tall, raising the mane and pressing the tail against the flank facing the opponent. Fighting between ♂♂ consists of highly ritualized head-on-head duels engaging the snout and tusks with sharp blows to sides of the head that are mostly taken on the warts. The mouth is closed and the sharp lower canines are seldom engaged in these encounters. However, they can be used, with typical suid sideways slashing movements, to good effect against predators.

Greeting behaviour takes the form of naso-nasal or naso-oral contact and sniffing or touching areas of glandular secretion such as the upper lip and the preorbital area (Cumming 1975) and naso-anal contact between warthogs was reported by Frädriich (1975). Subsequent amicable behaviour may take the form of gentle frontal pushing, one animal placing its chin on the other's back, and sometimes play fighting in young animals (Cumming 1975).

Allogrooming, by drawing hairs through closed lips, occurs between family members and may serve to remove nits. Common Warthogs readily huddle together in cool weather and otherwise rest or lean on or against each other. Bouts of vigorous, playful sparring between littermates are frequent, particularly after wallowing. Warthogs are remarkably vocal and emit a wide range of grunts, squeaks and squeals that communicate, *inter alia*, alarm, threat-attack, greeting and submission. Courting ♂♂ emit a loud, rhythmic, almost explosive 'chant de coeur' that resembles the 'phut-phut' of a two-stroke engine. Estes (1991a) considers that clacking the canines together is a major component of the chant, but after watching and listening to a tame boar at close quarters (<1m) the present author believes the noise to be vocally generated (D. Cumming pers. obs.).

The mating system is promiscuous with a dominance hierarchy between roaming ♂♂ (Cumming 1975, Somers *et al.* 1995). During the mating season dominant boars will seek out oestrous ♀♀ by visiting and sniffing around holes during the morning and very occasionally sleeping in the same hole at night (Cumming 1975). Courtship follows a typical suid pattern with a chanting boar following an oestrous ♀ and showing a typical courtship gait followed by resting his chin on her rump until she responds by standing still and allowing him to mount. A vaginal plug is formed after coitus, which may serve to lower risk of insemination from other ♂♂ (Mason 1982); mounting time is about 3 min (Somers *et al.* 1995).

Sows farrow on their own in burrows where their young remain, except when moving to another burrow or playing at the entrance, for the first one to two weeks. Thereafter they increasingly accompany the mother away from the hole for longer periods until they are about seven weeks old when they accompany the mother throughout the day. Although they begin grazing within a few weeks of birth, nursing continues until 3–4 months of age. A strict teat order, as in domestic pigs, has been observed in litters of tame Common Warthogs, with teats drying up on the loss of a member of the litter. Similarly, the number of developed and secreting mammary glands in captured wild animals corresponded to the number of young in the litter (D. Cumming pers. obs.). However, allo-mothering and allosuckling has been reported and studied in wild warthogs (Radke 1991a, Somers *et al.* 1995, Plesner-Jensen *et al.* 1999).

Reproduction and Population Structure Over much of their range breeding is seasonal, with mating at the end of the wet season and births near the start of the following rains. In southern Africa this equates to roughly Oct to early Dec (Cumming 1975, Boshe 1981, Mason 1982, Somers *et al.* 1995). However, close to the Equator breeding may occur throughout the year (Clough 1969). Oestrous lasts up to 72 hours (Clough 1969); oestrous cycle in captives in European zoos lasts about 35 days (Berger *et al.* 2006). The gestation period is about 170 days (Brown 1936, Child *et al.* 1968, Mason 1982). Litter-size is usually 1–4, most often three, but up to eight is recorded (Child *et al.* 1968, Mason 1982, Somers & Penzhorn 1992). Prenatal mortality may be marked, with reports of 9% mortality by Mason (1982) in KwaZulu–Natal and 17% by Child *et al.* (1968) in Zimbabwe. Sex ratio at birth is parity (Child *et al.* 1968) with the proportion of ♂♂ declining in older age classes (Cumming 1975). Birth-weight varies inversely with litter-size: Bigourdan (1948) recorded birth-weights of 480–620 g in larger litters (3–4) and 800–850 g in small litters (twins).

Both ♂♂ and ♀♀ reach sexual maturity at 18 months, with sows producing their first litter at two years old (Boshe 1981, Mason 1986). Males have been recorded mating at the age of 18 months but older boars usually dominate courtship and are presumed to carry out most mating. Growth in body mass is influenced by season, with a high growth rate during the wet season and markedly reduced growth rate in yearlings and subadults during the dry season (D. Cumming pers. obs.). Adult body size and weight is reached at between 36 and 48 months. Adult weight may fluctuate seasonally, with adult ♂♂ losing as much as 20% of their weight through the rut and the following dry season.

Tooth eruption patterns in seasonally breeding populations allow Common Warthogs to be aged to the nearest two months up to the age of 48 months (Child *et al.* 1965). Ageing of older animals is problematic and criteria developed by Spinage & Jolly (1974), based on the ratio of length to height of the third molar, were found to greatly underestimate the age of known-age material from the Sengwa area (D. Cumming pers. obs.) and in KwaZulu–Natal (Mason 1984). An alternative measure using the exposed height of the anterior edge of the third molar in relation to molar length promises to provide a more consistent and useful means of estimating the age of animals older than 48 months (D. Cumming pers. obs.). Mason (1984) found reasonably clear annual cementum lines in the incisors of known-age individuals from the Sengwa area. Common Warthogs may live 18–20 years in captivity (Jones 1993, Weigl 2005), but seldom reach 12 years in the wild. Boshe (1984), using age criteria developed by Spinage & Jolly (1974), calculated life tables for Common Warthogs in the eastern Selous G. R. that were derived from found skulls and a randomly selected sample of shot animals. He found a typical mammalian pattern of high early mortality, reduced mortality in the middle age classes, followed by increasing mortality rates as animals aged.

A population growth rate of 19% per annum was recorded in the Sengwa wildlife research area over a period of five years after which predation by Lions *Panthera leo* reduced the population by 50% per annum in two successive years. Somers & Penzhorn (1992) recorded a population growth rate of 39% per annum in an introduced population subject to minimal predation in the Eastern Cape of South Africa.

Predators, Parasites and Diseases Lions, where they occur, are undoubtedly the major predators of Common Warthogs and this conclusion is supported by several sets of records of natural mortality in Common Warthog populations. In five data sets summarized by Cumming (1975), Lions accounted for between 73 and 100% of predator kills. Other mammalian predators, in order of importance, included Leopards *Panthera pardus*, African Wild Dogs *Lycaon pictus*, hyaenas and Cheetahs *Acinonyx jubatus*. Martial Eagles *Polemaetus bellicosus* have been recorded taking piglets. Schaller (1972), in his study of the Serengeti Lion, concluded that Common Warthogs were highly susceptible to predation because of their lack of height, speed and caution. Lion prides are also capable of becoming 'warthog specialists' and in the Sengwa area Common Warthogs formed some 50% of Lion diet (i.e. in terms of carcass weight) during the late 1960s and early 1970s and about one-third of the animals killed were dug out of their holes.

Common Warthogs are reportedly very susceptible to rinderpest. During the great rinderpest epidemic of 1895–96 populations in southern Africa were greatly depleted and similar impacts were experienced in several West and central African countries during the 1980s (including Benin, Central African Republic and DR Congo). They are unaffected by diseases such as trypanosomiasis and swine fever. Tuberculosis has been recorded in Common Warthogs in Queen Elizabeth N. P., Uganda, and in Kruger N. P., South Africa (Wildlife Tuberculosis Study Group 2002).

Common Warthogs are hosts to a large number of endo- and ectoparasites. Oxpeckers *Buphagus* spp. will remove ticks from warthogs and hand-reared Southern Ground-hornbills *Bucorvus leadbeateri* were observed grooming members of a sounder on ten occasions during which some of the warthogs solicited grooming (Coetzee 2010). Some 65 species of tick have been collected from Common Warthogs across Africa (Cumming 1998). The soft tick *Ornithodoros moubata* feeds on Common Warthogs in their burrows and is responsible for the transmission of relapsing fever in humans and swine fever in pigs. At least three species of flea and one host-specific louse *Haematopinus phacochoeri* feed on Common Warthogs and very high populations of fleas can build up in their burrows. Standing at the entrance to a warthog hole that has not been used for a while can result in a 'mini-sandstorm' of fleas colliding against one's legs. Common Warthogs are also a preferred host of the tsetse fly *Glossina morsitans* (and see Conservation).

In southern Africa, at least 23 species of nematode, six species of cestodes and two species of trematodes have been found in Common Warthogs (Ortlepp 1964, Horak *et al.* 1983a, 1988a, Palmieri *et al.* 1985, Boomker 1990, Boomker *et al.* 1991a). Hydatid cysts of *Echinococcus* spp. have been found in the abdominal cavity of animals in Selous G. R. (Rodgers 1984a), in Kruger N. P. (Horak *et al.* 1988a) and in the Sengwa Wildlife Research Area (D. Cumming pers. obs.).

Conservation IUCN: Least Concern. CITES: Not listed.

The Common Warthog is present in numerous protected areas across its extensive range. However, because of their susceptibility to drought and predation, local populations may, as the work of Somers & Penzhorn (1992) and Somers (1997) suggests, be more prone to extinction than is generally appreciated. Hunting is a particular threat in some parts of their range. In Djibouti, the range of the threatened *P. a. aeliani*, Common Warthogs were the target of heavy hunting pressure before the implementation of a hunting ban in 1977; the maintenance of their habitat in the Goda Mts is essential for the survival of this population (Künzel *et al.* 2000). There is small-scale trade of Common Warthog tusks in some African countries, but no significant international trade in ivory has been documented (Vercammen & Mason 1993).

Common Warthog eradication was vigorously promoted in East Africa to control African swine fever (De Tray 1957), although their role in the transmission of the disease to domestic pigs had not been conclusively demonstrated. Selective game elimination as a means of controlling tsetse fly, the vector of ngana or trypanosomiasis in livestock, also eradicated or depleted Common Warthogs over large areas in East and southern Africa from the 1930s to the 1970s; for example, a total of nearly 68,000 Common Warthogs were shot in Zimbabwe between 1933 and 1957/1958 (Child & Riney 1987).

Measurements

Phacochoerus africanus

HB (♂ ♂): 1323 (1165–1440) mm, n = 56

HB (♀ ♀): 1182 (1090–1268) mm, n = 74

HF c.u. (♂ ♂): 264 (242–280) mm, n = 56

HF c.u. (♀ ♀): 247 (225–262) mm, n = 74

Sh. ht (♂ ♂): 682 (612–720) mm, n = 56

Sh. ht (♀ ♀): 598 (543–657) mm, n = 74

WT (♂ ♂): 79.6 (59.3–103.9) kg, n = 56

WT (♀ ♀): 56.5 (44.6–69.1) kg, n = 74

Hluhluwe G. R., KwaZulu–Natal (Mason 1985)

Body mass, and head and body length of 16 adult ♂ ♂ and 89 adult ♀ ♀ from the Sengwa Wildlife Research Area, Zimbabwe (Cumming 1975), and the body mass of 19 adult ♂ ♂ and 24 adult ♀ ♀ from Selous G. R. (Rodgers 1984a) and 68 ♂ ♂ and 74 ♀ ♀ from E Zambia (Wilson 1968), did not differ significantly from these measurements. The record length for a tusk, measured along the outer curve from the base to the tip, is 609.6 mm (the date and locality of the tusk are not recorded). For 5- to 8-year-old ♂ ♂, more typical lengths of the canine protruding from the gum line would be 120–200 mm

Suborder WHIPPOMORPHA – Hippopotamuses, Cetaceans

Whippomorpha Waddell, Okada & Hasegawa, 1999. Syst. Biol. 48: 2.

The discovery, by geneticists, that whales have derived from an early form of artiodactyl has created upheavals in several fields of biology, but most intensively in nomenclature, where most biologists had become accustomed to a long-established consensus on what to call such well-known animals as cloven-hoofed artiodactyls and the Cetacea (whales and dolphins). Revisions of subspecies and species have been more readily accommodated than the renaming of entire orders. Thus, many biologists are reluctant to change names and ranks that have a hundred years or more of precedent behind them. One compromise has been to avoid the use of ranks and use 'clade' rather than a specific ranked taxon for one of the new groupings revealed by molecular research.

Because the majority of taxa in *Mammals of Africa* follow established practice we have retained ranked taxa, following whatever recent authorities seem in possession of the most facts, parameters and most willing to allocate each newly recognized clade a position within its lineage's evolutionary tree. Thus, we treat Whippomorpha as the cetartiodactyl clade that contains the Hippopotamidae and Cetacea, and we treat it as a suborder within the Cetartiodactyla to give taxonomic recognition to some of the many new discoveries in molecular, palaeontological and other studies. The monophyly of this group is now well supported by concatenated mitochondrial and nuclear gene sequences (e.g. Amrine-Madsen *et al.* 2003, Meredith *et al.* 2011), complete mitochondrial genomes (Arnason *et al.* 2004, Hassanin *et al.* 2012) and retroposons (Nikaido *et al.* 1999), and has also been recovered in morphological phylogenetic analyses of living and extinct cetartiodactyls (Geisler & Uhen 2003, 2005) as well as supertree analyses (Beck *et al.* 2006) and combined molecular-morphological analyses (Spaulding *et al.* 2009). Aside from a few uniquely shared dental and skeletal structures (Geisler & Uhen 2003), hippos and whales also lack sebaceous glands and have very little (if any) hair, and these features may have been present in a common semi-aquatic ancestor (Gatesy *et al.* 1996, Geisler & Uhen 2003). Gatesy *et al.* (1996) have also called attention to the fact that hippos and whales both vocalize, and nurse their young, while underwater. Geisler & Uhen's (2003) character optimizations suggested that the last common ancestor of Whippomorpha was both herbivorous and at least partially aquatic, implying that a shift to a piscivorous diet in archaeocete whales occurred after, and not before, their shift from terrestrial to semi-aquatic habitus.

The most primitive fossil cetaceans are from southern Asia, as is the most generalized cetartiodactyl (*Diacodexis* = '*Gujaratia*' *pakistanensis*) and various other basal members of cetartiodactyl clades – together probably Asian. Whippomorph origins otherwise remain mysterious; the oldest cetacean is the ~53.5-million-year-old (early Eocene) *Himalayacetus* from India (Bajpai & Gingerich 1998), while the oldest definitive hippopotamid is *Morotochoerus*, which first appears around 21.0 mya, in the Early Miocene of East Africa (Orliac *et al.* 2010). Boissérie *et al.* (2004, 2005) have argued that this extensive hippopotamid ghost lineage can be filled in by members of the extinct anthracotheriid

Skeleton of *Elomeryx* (from Scott 1894).

radiation, members of which have been found in Asia, North America, Europe and Africa. In particular, they place the late Miocene bothriodontine anthracotheriid genera *Merycopotamus*, from Asia, and *Libycosaurus*, from Africa, as successive sister taxa of Hippopotamidae. However, the much larger sample of taxa (73 as opposed to 32) and morphological characters (208 as opposed to 80) compiled by Geisler & Uhen (2005) placed the bothriodontine *Elomeryx* as a stem member of Suina, and not of Hippopotamidae (although their study sampled only this one anthracotheriid genus, and not *Merycopotamus* or *Libycosaurus*). Furthermore, Geisler & Uhen (2005) found support for a placement of European Palaeogene *Cebochoerus* and Eocene Asian raoellids as basal whippomorphs, whereas Boissérie *et al.*'s (2005) analysis placed *Cebochoerus* outside of a suoid–cetartiodactyl clade, and did not sample raoellids. The more recent analyses of Thewissen *et al.* (2007) and Spaulding *et al.* (2009) place the raoellid *Indohyus* as the most basal stem cetacean, but situate anthracotheriids far from whales in other positions among non-cetacean artiodactyls. Anthracotheriids, cebochoerids and raoellids clearly all deserve consideration as possible stem or crown members of Whippomorpha, but their relationships can only be resolved through more fossil discoveries and more detailed phylogenetic analyses of the cetartiodactyl radiation.

The oldest fossil whales from Africa have been found in Egypt, Nigeria and Togo, and date to about 45–43 mya (middle Eocene). Anthracotheriids are the only other possible whippomorphs that were present in Africa during the Palaeogene, and probably dispersed there from Asia in the late Eocene, about 36 mya.

The name Whippomorpha, an amalgam of whale and hippo, has not had universal acceptance and Arnason *et al.* (2000) have proposed 'Cetancodonta' for the same entity. However, Whippomorpha has priority (see Asher & Helgen 2010) and is accepted here.

Erik R. Seiffert & Jonathan Kingdon

Infraorder ANCODONTA – Hippopotamuses

Ancodonta Matthew, 1929. Geol. Soc. Am. Bull. 40: 406.

Ancodonta was established by Matthew (1929) for primitive, tetradactyl, selenodont artiodactyls such as the caenotheres, anthracotheres and oreodonts, but has often been regarded as a subdivision of the Suiformes (McKenna & Bell 1997). Ancodonta is here provisionally interpreted as an infraorder of the Whippomorpha and includes hippos (Hippopotamidae) and anthracotheres (Anthracotheriidae), both of which have significant fossil records in Africa.

The origins of the Hippopotamidae have been hotly debated over the years, with Colbert (1935) championing derivation from the anthracotheres, and Pickford (1983, 1989, 1993) from the peccaries and other suoids. During the past decade, genetic evidence has linked hippos closely with the whales (Gatesy 1998, Ursing & Arnason 1998, Nikaido *et al.* 1999), much to the consternation of some palaeontologists because of the 40-million-year gap between the tetrapod cetaceans of the early Eocene and earliest hippos from the Early Miocene. Nevertheless, recent fossil evidence and morphological studies show close similarities between the limbs of early whales and those of early artiodactyls (Gingerich *et al.* 2001, Naylor & Adams 2001, Thewissen *et al.* 2001). Morphologically based cladistic analysis by Boissérie *et al.* (2005) has now confirmed close relationship between early cetaceans and basal anthracotheres on one hand and between advanced bothriodontine anthracotheres and hippos on the other, thereby validating Ancodonta as a coherent entity within the Whippomorpha.

The anthracotheres were a primitive group of medium- to large-sized browsing artiodactyls that were widely distributed across Eurasia and parts of Africa during much of the Cenozoic, but with a more restricted distribution (middle Eocene to middle Miocene) in North America (Kron & Manning 1998). Anthracothere skulls were often slender with elongated muzzles, robust zygomatic arches, prominent supraoccipital tubercles and elevated sagittal crests (Boissérie *et al.* 2005). Most anthracothere species retained a full complement of teeth although some displayed a reduction in number of incisors and one of the last African anthracotheres (*Libycosaurus pettochii*) evolved a fifth premolar (Lihoreau *et al.* 2006). The canines were often large and sometimes sexually dimorphic. The upper molars are wide and frequently pentacuspitate though sometimes quadricuspitate. They vary from bunoselenodont to fully selenodont and the taxon is generally divided into two clades – Anthracotheriinae and Bothriodontinae – with the latter having a more derived selenodont dentition. The limbs are short and robust and the forelimbs vary from pentadactyl to tetradactyl.

The oldest anthracotheres derive from the middle Eocene of South-East Asia, but are subsequently found elsewhere in Asia and in Europe, Africa and North America (Ducrocq *et al.* 2000). In Africa they are known from the late Eocene or early Oligocene of the Fayum in Egypt (Ducrocq 1997) and persist until the late Miocene (Vignaud

ABOVE: Skeleton of *Rhodocetus*, an early fossil whale (after Gingerich *et al.* 2001).

BELOW: Skeleton of Common Hippopotamus *Hippopotamus amphibius*.

et al. 2002). They were significant elements of the early Miocene assemblages of eastern and southern Africa, but have not been recovered south of the Sahara from sites younger than the middle Miocene. Anthracotheres have been interpreted as water-dependent or semi-aquatic based on their abundance in lignites and fluvio-lacustrine deposits (Pickford 1991). Lihoreau *et al.* (2006) have drawn attention to features such as elevated orbits and nostrils, long auditory tube and dense tympanic bullae, that suggest *Libycosaurus* species behaved similarly to the hippopotamids. That anthracotheres disappear from the fossil record at about the same time that hippos make their first appearance may suggest some kind of functional/behavioural replacement, but, as indicated above, Boissérie *et al.* (2005) have argued that anthracothere-like animals were indeed closely related precursors to hippopotami. Nevertheless, it would appear unwise to include anthracotheres within the direct lineage of living hippos as Bronner *et al.* (2003) implied by treating anthracotheres as a superfamily, the Anthracotheroidea, and interposing this taxon between the Ancodonta and Hippopotamidae.

John M. Harris

Family HIPPOPOTAMIDAE
HIPPOPOTAMUSES

Hippopotamidae Gray, 1821. London Med. Repos. 15: 306.

| | | |
|---------------------------------|---------------------|-------|
| <i>Hippopotamus</i> (1 species) | Common Hippopotamus | p. 64 |
| <i>Choeropsis</i> (1 species) | Pygmy Hippopotamus | p. 78 |

The Common Hippopotamus *Hippopotamus amphibius* is well known as a large, bulky, naked-skinned, herbivorous mammal with a wide mouth and dangerous lower tusks, which spends much of its life in water. Today, it is an exclusively sub-Saharan African species, although several centuries ago it was to be found down the Nile R. to its delta. A second living species is the Pygmy Hippopotamus *Choeropsis liberiensis* (sometimes included in the genus *Hexaprotodon*) from West Africa. This species differs by its smaller size, only two instead of four incisors in the lower jaw, a shorter face, and other characters elaborated upon in the species profile. Both species have four toes on each foot supporting the body weight, with all digits more or less equally well developed.

Common Hippopotamus *Hippopotamus amphibius* sole of hindfoot.

In the scientific history of the hippopotamuses (hereafter hippos), the Pliocene *Hexaprotodon* was long thought to be a pivotal fossil. Its type species *Hexaprotodon sivalensis*, found in India, had been described as early as 1836, and was smaller and more primitive than the Common Hippopotamus. The then new subgenus, as was implicit in its name, had a total of six upper and six lower incisors (hexaprotodonty) in contrast to only four of each (tetraprotodonty) in *Hippopotamus amphibius*. Subsequently, many fossil species of *Hexaprotodon* were collected, especially in Africa. They were predated by the earliest-known hippopotamus, represented by some small and low-crowned teeth from several sites in East Africa: *Morotochoerus*, dated to around 21.0 mya (Orliac *et al.* 2010) and *Kenyapotamus*, from 16.0–8.5 mya (Pickford 1989).

As an attempt to improve hippopotamus classification, Boisserie (2005) confined use of *Hexaprotodon* largely to Indian and South-East Asian species, and founded two more genera, *Saotherium* and *Archaeopotamus*. The first was a newly discovered fossil relative of *Choeropsis* from about 5.0–4.0 mya in Chad, which demonstrated the long separation of this stock from all other hippos. *Archaeopotamus* embraced early hippos with narrow muzzles and shorter faces, unlike the living *Hippopotamus amphibius*. Many subsequent changes centred on the front of the mandible, where the canine roots are thrust forward and outward, increasing the size of the canines and decreasing the

Profile and dorsal views of Pygmy Hippopotamus *Choeropsis liberiensis*, Common Hippopotamus *Hippopotamus amphibius* and *Hippopotamus gorgops* (from Kingdon 1982).

number of incisors. More than one evolution of tetraprotodonty took place and specialized diprotodont (two-incisored) hippos also appeared. Various Pliocene and Pleistocene species extended into western and southern Europe and, at intervals, as far north as N England and as far east as Georgia. Other branches of the evolutionary tree led to various dwarfed forms on some Mediterranean islands and on Madagascar, and to specialized large species like the East African *Hippopotamus gorgops* with periscopically raised orbits. This last species, or a parallel to it, has also been found among the European Pleistocene species in Europe. It seems to have been a feature of hippopotamus evolution that African species have often been endemic to particular drainage basins, in contrast to the present-day post-Pleistocene situation.

Hippos appear rather late in the fossil record (Theodor *et al.* 2005) and their relationship to other artiodactyl families is still being clarified. A slow-moving discussion over many decades (Colbert 1935, Kron & Manning 1998) has debated whether hippos share an immediate common ancestry with suoids (pigs and peccaries, appearing at around 35 mya), or with a different and extinct artiodactyl group, the anthracotheres, which go back to about 45 mya. Then, in the last decade of the twentieth century, came a startling development. Researchers into molecular phylogeny began to find resemblances of hippos to

whales and of the combined hippopotamus–whale group to ruminants (Gatesy *et al.* 1999, Ursing *et al.* 2000). Previously it had been accepted that archaic ungulate mammals called Mesonychidae were the sister-group or closest relatives of whales and that mesonychids and whales together were related to the artiodactyls. However, if whales and presumably mesonychids are to be closely related to hippos and then to ruminants, then the ancestor of whales would already have been an artiodactyl. Otherwise, pigs, peccaries and camels would have to constitute a separate order from other artiodactyls.

The assertion of a relationship between whales and hippos implies a primary importance for adaptations to aquatic life. Perhaps both groups evolved aquatic adaptations that were then carried much further in whales. Alternatively, the genes that hippos shared with the earliest more terrestrial whales might have allowed them readily to take up the opportunity of a life in and near water, even if the pig-related or anthracothere-related intermediates were more or less terrestrial. The intricacies of molecular data are perplexing and much will depend on understanding the sequences of bases (nucleotides)

along genes, the frequency with which they might mutate and back-mutate over thousands and millions of years, whether or not they are affected by natural selection, and the conditions governing movements or transfers of pieces of genetic material.

Within this flux, the old question continues of whether anthracotheres or pigs provide the continuity back from the earliest hippos to other artiodactyls. Boissérie *et al.* (2005) nested hippos within selenodont (= having crescentic-crested teeth) anthracotheres, then linked them to whales, then to pigs and peccaries, and only then to ruminants. The debate will certainly continue. It would be interesting to know how hippos, with or without whales in tow, connect with the family Tragulidae (chevrotains). The latter are small and primitive ruminants and still extant. Like anthracotheres they are poised between bunodonta (teeth with low rounded cusps) and selenodonta, and like hippos they had been supposed until recently to make another unusually late appearance in the fossil record.

Alan Gentry

GENUS *Hippopotamus* Common Hippopotamus

Hippopotamus Linnaeus, 1758. Syst. Nat., 10th edn, 1: 74.

Common Hippopotamus *Hippopotamus amphibius* myology of head.

There is only one living species of *Hippopotamus*, namely *H. amphibius*, which is now confined to sub-Saharan Africa (though it formerly occurred also in the Nile Delta). Dominant features of *Hippopotamus* include a barrel-shaped body, disproportionately short limbs and a large head with the eyes, ears and nostrils high up on the skull so that the animal can see, hear and breathe when almost completely submerged in the water, a condition correlated with life at the interface between water and air. All species of this genus are characterized by four incisors on both upper and lower jaws with strong development of the first lower incisors and of the canines; the enamel on the lower canines exhibits strong, convergent ridges (these ridges are diagnostic for *Hippopotamus*). It is literally amphibious, spending much of the day in lakes or rivers, which it leaves at night to graze away from the

water. Its physiology ties it to water as the skin dries and cracks if exposed to prolonged sunlight and desiccation.

The earliest hippopotamids, from outside Africa, date from the Early Miocene, but by the Pleistocene the genus *Hippopotamus*, with at least six species, was widespread throughout Eurasia although it never reached the Americas or Australia (Coryndon 1967). As with other hippopotamid lineages, there has been a great reduction in both the geographical range and in the number of *Hippopotamus* species (more than ten fossil species have been recognized). During the Pleistocene, the genus extended to Mediterranean islands and Europe north as far as England and Germany and east as far as the Caucasus. It apparently never spread far into Asia, where the genus *Hexaprotodon* dominated from the late Miocene until the late Pleistocene.

Many fossil *Hippopotamus* species have been recovered from East Africa, partly because of intense palaeontological activity in this region and an abundance of lakes and riverine flats in a volcanic region. Securely identified oldest remains of *Hippopotamus* are from late Pliocene deposits in the Western Rift Valley, and were attributed to *H. kaisensis*. This was similar, if not identical, to the living species (Pavakis 1990). Harris *et al.* (1988) and Faure (1994) also refer some early Pliocene remains from Turkana (Kenya) and Nkondo (Uganda), respectively, to *H. kaisensis*. A *Hippopotamus* sp. tentatively identified as *H. kaisensis* has also been reported in early Pleistocene deposits in Malawi (Bromage *et al.* 1995). The earlier, fragmentary African fossils are not clearly identifiable as to genera, a situation obscuring for now the origin of *Hippopotamus* (Pavakis 1990, Gentry 1999). Among other hippopotamids, Plio-Pleistocene species from Turkana and Afar Basins are anatomically the most similar to *Hippopotamus* (Boissérie 2005). Some shared characters, such as elevated orbits or development of particularly extended canine bony sockets, clearly evolved in parallel in different lineages.

Hippopotamid remains have been found over much of East Africa (Coryndon 1973, Coryndon & Coppens 1973). The only fossil

Common Hippopotamus *Hippopotamus amphibius*, yawning displays and jaw-clashing. Note the main contact on the mandible.

Hippopotamus known from southern Africa are *H. amphibius* and *H. gorgops* from the middle to late Pleistocene (Cooke 1949, Hooijer 1958). It is likely that other fossil remains that are widespread in Africa represent undescribed species.

There are several recently extinct hippopotamids that showed island dwarfing including those on Malta and Cyprus. These Mediterranean dwarfs are close to *H. amphibius*, but have been assigned to separate species (Boekschoten & Sondaar 1972, Capasso Barbato & Petronio 1983). Two dwarfed forms on Madagascar described from sub-fossil remains, *H. madagascariensis* and *H. lemerlei*, have also been given specific status (Stuenkel 1989), although Fovet *et al.* (2011) suggest that *H. madagascariensis* is a synonym of *H. lemerlei* (and concomitantly propose a new species, *Hippopotamus guldbergi*, based on a skeleton formerly

attributed to *H. madagascariensis*). *Hippopotamus lemerlei* survived until about 1000 years ago (Dewar 1984, Burney *et al.* 2004). There was also a large species, *H. laloumena*, of Holocene age on Madagascar (Faure & Guérin 1990), but it may reflect an invasion of *H. amphibius* from mainland Africa (Burney *et al.* 2004). This colonization and the discovery of hippos well out to sea confirm its ability to swim and disperse.

It is interesting that during the middle Pleistocene a cranially more archaic species, the extant *H. amphibius*, should have replaced more highly specialized species, among them *Hippopotamus gorgops*. A prime advantage would seem to have been the living species' possession of dentally more derived (higher-crowned) cheekteeth, implying that a greater ability to survive on coarser forage has been decisive. Another implication is that hippos seem to have evolved

Evolution of *Hippopotamus gorgops* at Olduvai (after Coryndon 1970).

to occupy more constrained and constricted niches than those they occupy today. Modern-day *H. amphibius* presumably now occupies a broader niche than it once did.

Hippopotamus gorgops, named for its protuberant, periscope-like eyes, exemplifies several of the most extreme features of its genus (Coryndon 1971). The trend towards ever-heavier, longer lower jaws, but lighter, shallower skulls is well illustrated by a series of fossils of *Hippopotamus gorgops* from 1.8, 1.5 and 0.7 mya, all from Olduvai. Correlated with the heavy lower jaw and its multiple functions, there have been extraordinary reorganizations of articulation between lower and upper jaws (and between skull and backbone) as well as wide expansion at the front of both jaws. The adaptive function of these uniquely hippopotamid peculiarities can all be related to an intensely social life, especially intra-specific competition among ♂♂ fighting for mating rights in confined, relatively shallow waters. With bodies immersed in water or mud, but eyes and muzzle above the surface, dominant individuals snap at one another or threaten with open jaws on or above the water's surface and each tries to catch or engage its opponent's jaws. The outcome of fights, for both contestants, depends on testing strength, weight and the ability to ram, bite or engage with the teeth in a manner analogous to antler-clashing. Since the lower jaw must simultaneously serve as a weapon of offence as well as defence, the incisors and canine teeth (and their bony sleeves) have made a phylogenetic increase in size and breadth to withstand the impact of up to 3000 kg of biomass behind

Diagram of the skull and lower jaw rotation on the first cervical vertebra.

an assault (Kingdon 1979). The celebrated hippo 'yawn' probably serves several social purposes, but among them must encode telling information about the yawner's status.

Hippopotamus is almost unique in evolving a mandible that is heavier than the skull above it and this peculiarity has clearly evolved to both deliver and absorb the main force of such jaw clashes. While the entire body, especially the neck and champing muscles, provide the weight and power behind contests, the neck-skull and skull-jaw articulations would be vulnerable to dislocation were it not for the mandibular condyle migrating to the very back of a heavily reinforced cranium. Here, the condyles are close to the occipital junction with a large and cup-like atlas (first of the cervical vertebrae, all of which are exceptionally dense and compact). This arrangement allows the entire body to deliver and absorb jaw clashes and it also permits the cranial part of the skull to jack-knife vertically upwards while the mandible remains horizontal, a uniquely hippopotamid capacity.

Hippo species have varied in the number, size and orientation of their incisors, sometimes within a species, most notably in *H. amphibius* (Coryndon 1970). Hexaprotodont hippos keep the full complement of six incisors, tetraprotodonts have four, while diprotodonts have reduced their incisors to two. Perhaps the most extreme example of expansion at its front end is the mandible of a highly aquatic

Common Hippopotamus *Hippopotamus amphibius* gaping skull (left) and reinforced front of mandible (right).

Pleistocene diprotodont hippo, aff. *Hippopotamus karumensis*, where relatively small canines are encased in disproportionately heavy, projecting, antler-like bony sheaths. The single pair of remaining incisors instead are long, massive and also resemble the tines of an antler. Thus, the front end of the mandible (and upper jaw) has widened in every hippo species and genus, with many permutations of tooth proportions, presenting a flattened (but toothy) frontal plane that in some respects resembles the bull-bars attached to heavy cross-country vehicles.

As with any other mammal, a hippo skull accommodates visual, auditory and other sensory equipment, a brain and a battery of masticatory teeth together with all the musculature and anchorage to serve or encase all these functions. In terms of the hippos' external forms, all such functions have become subordinate to weight and aggression-testing behaviour in very large amphibious animals. Front teeth that once took bites of food have been elaborated in various ways to serve these agonistic purposes, leaving the lips to take over the function of cropping. The swollen, flat-fronted mouths that characterize all species in this genus therefore reconcile both cropping and hydrodynamic properties as well as providing a covering for one of the most extraordinary elaborations of incisor and canine teeth to be found in any mammal.

Hippopotamus amphibius COMMON HIPPOPOTAMUS

Fr. Hippopotame; Ger. Flusspferd

Hippopotamus amphibius Linnaeus, 1758. Syst. Nat., 10th edn, 1: 74. 'Habitat in Nilo & Bambolo Africae et ad ostia fluviorum Asiae'; restricted to River Nile (Thomas 1911: 155) in Egypt (G.M. Allen 1939: 457).

Common Hippopotamus *Hippopotamus amphibius*.

Origin of name: Greek *hippos* = horse; *potamos* = river.

Taxonomy Five subspecies of Common Hippopotamus (hereafter Common Hippo) have been proposed (Lydekker 1915), based primarily on skull shape and proportions, but their validity is uncertain (Ansell 1972, Grubb 1993a, Eltringham 1993a, 1999); subspecies are never distinguished in published studies of Common Hippo ecology or behaviour. Grubb (1993a) noted that there has been no serious attempt to determine the geographic distribution of the species and that additional specimens need to be examined from a wider area in order to determine whether the diagnostic skull characters currently used to differentiate subspecies are more than just abnormalities of certain specimens. Likewise, Eltringham (1993a) remarks that subspecies cannot be distinguished in the field and that given ranges are indistinct. However, a study using mitochondrial DNA from skin biopsies (Okello *et al.* 2005) found low, but significant, genetic differentiation among *H. a. amphibius*, *capensis* and *kiboko*, thus confirming the subspecific division and nomenclature; *H. a. amphibius* is considered the ancestral group. Also, there is evidence that Common Hippos experienced a marked population expansion during or after the Pleistocene, due to an increase in water bodies at the end of this era. Provisional recognition of five subspecies here follows Grubb (1993a). Synonyms: *abyssinicus*, *australis*, *constrictor*, *senegalensis*, *typus*. Chromosome number: $2n = 36$ (Hsu & Benirschke 1977).

Description Unmistakable species, characterized by great barrel-shaped body, naked skin, and short, but stout, legs. Head broad and heavy, the eyes raised on bony sockets on top of the head, and raised

nostrils on top of the rhinarium. Ears are small relative to the size of the head. Body dark reddish-brown, ventral surface pink, with individual variations in extent of pink. Skin with fine short hair, 20–30 per 100 cm², especially on the back, with thick bristles on snout and tail, and sparse covering of hairs on sides of the head and neck, lips and tips of ears. The tail is short and flattened. There are four toes on each foot, with each toe ending in a broad, heavy nail. Adult bulls are recognized by their strong muscular neck, proportionally larger head and, on the muzzle, prominent bulges accommodating the lower canines; ♂♂ are about 10% heavier than ♀♀ (Eltringham 1999). Females have one pair inguinal nipples.

The skull is characterized by a small braincase, high supraorbital ridges (associated with the position of the eyes on top of the head), and high supraoccipital and sagittal crests. The postorbital bar is complete in old specimens, usually with a distinct bony knob at the junction of the two bones. The zygomatic arches are thick and swing outwards at the back, giving room for the temporalis muscles. The massive zygoma give firm anchorage for the masseter muscles, while the high supraoccipital and sagittal crests extend the surface of the sides of the small braincase for the attachment of the large temporalis muscles that pass through the massive zygomatic arch. The temporalis and masseter muscles need to be particularly powerful to lever the massive lower jaw with its accompanying huge, heavy teeth (which may have a mass of up to 16 kg) (Eltringham 1999, Skinner & Chimimba 2005).

The dental formula is $I^{2/2}, C^{1/1}, P^{3-4/3-4}, M^{3/3} = 36-40$, reduced from the ancestral 44. Common Hippos carry four formidable, tusk-like canines, and eight shorter and more rounded incisors. Both canines and incisors have open roots and continue to grow throughout life. The canines in the lower jaw are the largest and

Lateral, dorsal and palatal views of skull of Common Hippopotamus *Hippopotamus amphibius*.

heaviest of the teeth. They are triangular in section, with the flat face on the inner side, and are distinctly ridged along their length. The canines in the upper jaw, through wear, remain short but very sharp-edged. The inner face of the canines, through occlusion with its short counterpart in the upper jaw, is continually honed to a flat surface, keeping the point and sides of the tooth sharp. Canines project for about 300 mm from the gum, although the root may be some 400 mm in length, bringing the total to 700 mm. The incisors, like the canines, wear by occlusion on their inner faces, and remain round and blunt-pointed. The outer incisors are larger than the inner pair. The upper incisors are rounded, while those in the lower jaw are triangular in cross-section. The canines in ♂♂ are markedly larger than those of ♀♀. Neither the incisors nor the canines are used in feeding, this job falling to the cheekteeth. The molars are roughly squarish, with a cusp in each quarter (Eltringham 1999, Skinner & Chimimba 2005).

At birth Common Hippos appear to have only the central incisors and canines protruding through the gums. These are shed within the first few months of their life. Four deciduous premolars may be present below bone level. The second, third and fourth are replaced by permanent teeth; the first is present only in the milk set and not subsequently replaced, although it often persists quite late in life; when retained, the tooth is small and vestigial, and separated from the other premolars by a diastema (Eltringham 1999, Skinner & Chimimba 2005).

Geographic Variation

H. a. amphibius: Gambia east to Sudan, Ethiopia, N DR Congo, Tanzania and Mozambique; extinct in Egypt, where they occurred in the Nile Delta and on the lower Nile R. (and may have represented a distinct subspecies; see Manlius 2000a). Skull with moderate preorbital

Common Hippopotamus *Hippopotamus amphibius* myology.

constriction, convex upper surface, long mandibular symphysis and relatively large cheekteeth (Grubb 1993a).

H. a. tschadensis: Chad and Nigeria. Similar to nominate form, but with prominent orbits. Compared with *capensis*, has shorter and wider facial region and more forward direction of orbits (Grubb 1993a).

H. a. kiboko: Kenya and Somalia. Skull with broad nasals, relatively small rostral constriction, and elevation of orbits and occipital crest above the hollowed interorbital region. Orbits more circular than *capensis*, and more prominent than in *constrictus* (Grubb 1993a).

H. a. constrictus: Angola, S DR Congo and Namibia. Skull lighter than in typical race with preorbital constriction deeper, upper surface more flattened, muzzle less expanded, mandibular symphysis shorter and cheekteeth smaller (Grubb 1993a).

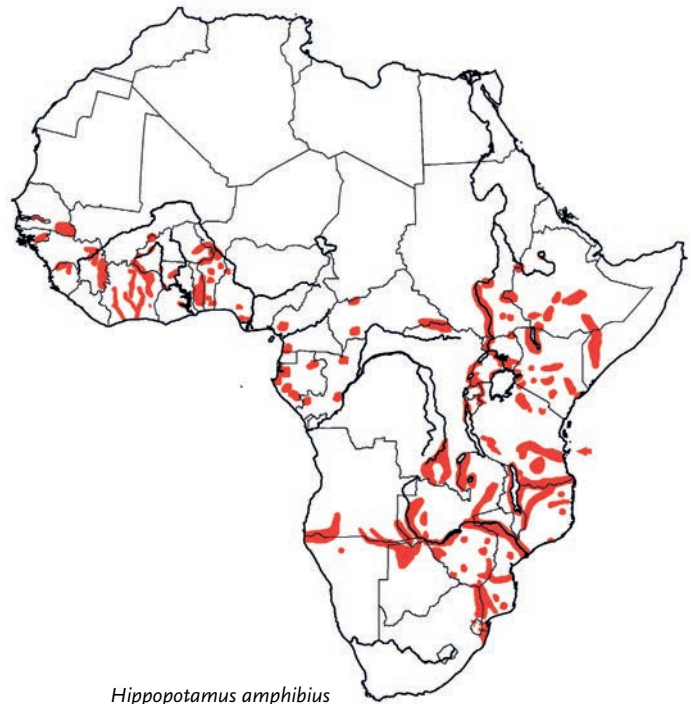

H. a. capensis: Zambia south to South Africa. Skull more flattened than in *tschadensis*, such that width of orbit is greater than height (Grubb 1993a).

Similar Species

Choeropsis liberiensis. Largely allopatric, although range overlaps with *H. amphibius* in the upper stretches of some rivers in Côte d'Ivoire (see Roth *et al.* 1996, 2004) and in NW Sierra Leone (Grubb *et al.* 1998). Smaller overall size, but with relatively longer limbs; one pair of lower incisors only; in the skull, the orbits are positioned on the side of the head and are situated in a more mid-way position along the length of the skull. For a comparative review of *Choeropsis* and *Hippopotamus* see Eltringham (1999).

Common Hippopotamus *Hippopotamus amphibius* variations in skin pigment (from Kingdon 1982).

Hippopotamus amphibius

Distribution Common Hippos are endemic to Africa, ranging widely over most of sub-Saharan Africa, from Senegal and Gambia in the west to Sudan, Ethiopia and Somalia in the east, and south to KwaZulu–Natal in NE South Africa, the Okavango Delta in Botswana and the Kunene R. in Namibia. They are restricted to suitable areas, i.e. grassland with river/lake/swamp; absent from rainforest except for rivers with adjacent grass patches.

In the past Common Hippos occurred in the Nile R. all the way to the Nile Delta, and up until 1700 were still present in two disjunct zones in the Nile Delta and in the upper Nile; the last definite records from Egypt come from the early 1800s, their disappearance principally caused by hunting (see Manlius 2000a). Common Hippos also occurred in the Sahara, and in South Africa right to the Cape where they have been wiped out in historic times (Kingdon 1979). In the recent past they have been locally eradicated or severely reduced (for example, the populations of the crater lakes around Dongobesh, Basodesh and Hanang in Tanganyika have completely vanished over the last 50 years; J. Kingdon pers. comm.), although the general range has not changed much (Eltringham 1999). Apparently, previously present on Mafia I., and possible that they still occasionally occur (see Kock & Stanley 2009 for discussion); excluded from the fauna of Zanzibar and Pemba by Pakenham (1984).

Habitat Common Hippos require water for thermoregulation and skin protection and are therefore never far from a water source, be it river, lake, swamp or wallow. Common Hippos feed predominantly on grasses, so their range is limited to grasslands and grassland–bushland mosaics within reach of water (even where they occur in saline water, grazing and freshwater are essential). They may use established pools over a period of many years, so long as there is sufficient food available and they remain undisturbed; seasonal flooding may cause them to move temporarily from their established resting pools. Jacobsen & Kleynhans (1993) demonstrated the importance of weirs as refuges for Common Hippos in South Africa's

Limpopo R., with 50% of all sightings of Hippos occurring along stretches of the river where weirs, which provide permanent water, are prevalent.

Abundance Common Hippo counts are bound to be inaccurate, as the subjects are usually submerged and do not synchronize their surfacing. Accurate figures can be obtained of individuals and groups when they are in shallow and/or clear water, and when they come on land during the day.

In 1988/1989 Keith Eltringham conducted an Africa-wide survey and estimated a total of 173,690 Common Hippos: West Africa (up to, and including, Chad, Central African Republic, Congo), 7750; East Africa (Ethiopia, Somalia, Kenya, Uganda, Sudan, DR Congo, Rwanda, Burundi, Tanzania), 79,550; and southern Africa (up to, and including, Mozambique, Malawi, Zambia and Angola), 86,400. Only some of the eastern and southern African populations in conservation areas were considered largely stable and reasonably secure. He reports that in 18 of the 34 countries in which surveys were conducted, populations were thought to be declining (Eltringham 1993a, 1999). Lewison (2004) conducted a similar survey and found that, continent-wide, Common Hippo populations have declined between 7 and 20% over the past ten years. This new estimate suggests that total populations are 125,000–148,000, with reported declines in 18 countries. Stable populations were reported in Chad, Ethiopia, Kenya, Malawi, South Africa, Tanzania and Zimbabwe, and increasing numbers only in Zambia. Largest numbers were found in Zambia (40,000), Tanzania (20,000–30,000), Mozambique (18,000) and Malawi (10,000).

Historically, the highest densities have been recorded in the Queen Elizabeth N. P., Uganda, with 28 individuals per km² of suitable grassland. The corresponding biomass amounts to 28 tonnes/km² (Field & Laws 1970). Even larger Common Hippo populations were found in Virunga N. P., DR Congo, in the 1970s (Delvingt 1978). However, civil unrest has resulted in a severe depletion (>90%) of the population in this park (Hillman Smith *et al.* 2003, Lewison 2006).

Adaptations Common Hippos are highly adapted to their amphibious life-style. The epidermis is thin (up to 1 mm thick on the back), and as it is very well supplied with nerve endings, is very sensitive and delicate. Common Hippos reacted strongly when hit with drops of paint ejected from a medical syringe (for marking) (H. Klingel pers. obs). Slight scratches from bushes often result in bleeding wounds that heal quickly. The epidermis dries and cracks easily, so must be kept moist. The dermis is up to 60 mm thick on the back and flanks, thinner on head, neck and belly, and is composed of fibrous collagen. The skin accounts for about 18% of total body weight. Hippos have no true sweat glands. However, a viscous alkaline secretion (pH 8.5–10.5), ranging from colourless to reddish-brown, is produced by large, subdermal glands (distributed at a density of about 1/cm²). This secretion imparts a pinkish tinge to the body and has antiseptic properties, preventing infections and sunburn and helping in thermoregulation (like sweat) (Luck & Wright 1964, Wright 1964, 1987, Eltringham 1999, Saikawa *et al.* 2004).

The skin serves to control body temperature primarily through regulation of evaporation, which is very high compared with other mammals, and is particularly high when the skin is wet with the secretion from the subdermal glands (Wright 1987). This led Eltringham (1999) to suggest that temperature control is not achieved through

Distribution of hippopotamus groups along a stretch of the Nile (near Chobe) (after Laws *et al.* 1975). Note solitary animals (nearly always males) scattered down both banks and large herds' preference for shallows near the mouths of tributaries.

any mechanism akin to sweating unless the secretion functions like sweat, and that they may not be able to control the rate of water loss from the body. Whether or not the secretion serves the same function as sweat, Common Hippos maintain a constant core body temperature of around 36°C even while on land (though body temperature is certainly also controlled by using its aquatic environment as a means of cooling off) (Eltringham 1999). When dry it gives a shiny varnish-like appearance.

When in the water, Common Hippos lift their slit-like nostrils up to the surface to breathe, at intervals of up to 6 min. A reflex response ensures that the nostrils and ears are closed as soon as they come into contact with water. By lifting the head above the water level, the ears, eyes and nostrils are allowing for visual, acoustic and olfactory perception. Because of the insulating properties of their thick skin, heat loss in the water is greatly reduced, the skin functioning as a 'diving suit'. This, however, is an obvious disadvantage when moving on land as it reduces metabolic heat dissipation. Therefore, Common Hippos undertake the long excursions to their grazing grounds during the cooler night hours.

Although Common Hippos spend much time in the water, they can neither float nor swim – at least there is no convincing evidence that they do in freshwater. They can even sink to the bottom fully inhaled, and they exhale under water or when they come up for the next breath. This can easily be observed in the wild. In Mzima Springs in Tsavo West N. P., Kenya, the Okavango in Botswana, and in some zoos, Common Hippos can be observed walking on the

Common Hippopotamus *Hippopotamus amphibius* skeleton.

bottom. Depending on the depth of the water, the animals lie in sternal recumbency on the bottom, either fully under or with just the tops of their backs showing; in deeper water they stand on all fours, and in even deeper water they stand on their hindlegs. To reach the surface, they either just lift the head or they push themselves off the bottom. Shallow water for the adults is deep water for the infants who have the option of standing on their hindlegs, pushing themselves up for breathing, or of sitting on their mothers' backs, apparently floating like a cork when the mother is submerged. It is quite possible that Common Hippos are able to swim in seawater, and that would explain their former appearance on Madagascar, Cyprus and Malta as well as on islands off the African coast. As the sea levels were lower during the Pleistocene than at present, the distances to be covered would have been considerably shorter. It is still a remarkable achievement for Common Hippos not only to have reached Madagascar, but also to have established viable populations there for tens of thousands of years. This achievement is even more impressive when one realizes that none of the many other ungulate species of Africa that are good to excellent swimmers ever managed to make it across to Madagascar.

The colonizing effort and success of Common Hippos on dry land is also quite remarkable. Examples are the population of the Basodesh–Dongobesh–Hanang craters in the driest part of Tanganyika and of the Ngorongoro population. The founders must have negotiated their way over long and unknown stretches of waterless terrain, and for Ngorongoro they climbed the outer crater slope and down the inner one. A journey of ca. 1800 km over a period of three years over unknown country was well documented in the South African press when, in the late 1920s, Huberta the Hippo travelled from L. St Lucia in KwaZulu–Natal to near Port Elizabeth (Chilvers 1931).

Common Hippos have a graviportal skeleton, being designed specifically to support their great weight. The bones of the skeleton are massive, particularly the spinal vertebrae, although the limb bones are not as heavy as may be expected in such a large animal (presumably because much of the weight of the Common Hippo is supported by water) (Eltringham 1999). When at ease, locomotion on dry land is a slow walk, each step being accompanied with a nod. When fleeing or attacking, Common Hippos perform a speedy trot and can exceed 30 km/h. Indeed, despite their heavy build, they are swift and agile and are able to climb steep slopes. Under water they move as on land except for the head nod, but, in addition, they can perform a series of forward jumps, pushing themselves up from the bottom, breaking the surface and diving in again, all in a seemingly dolphin-like manner and attaining impressive speeds that have not yet been timed.

Common Hippos spend most of the daylight hours resting and most of the night feeding. Activity pattern is influenced by weather. In dry, hot weather most animals come on land in the late morning to rest for several hours in the sun on the foreshore. In cool weather, and when it rains, they either stay in the water or come out to feed near the shore. At St Lucia in South Africa, Common Hippos, especially the subadults, bask mostly during the winter months when the water is coldest (R. Taylor pers. comm.). Where they are disturbed, generally outside protected areas, they stay in the water throughout the day. At dusk they leave the water and walk inland to their grazing areas, which can be up to 10 km from the shore (Kingdon 1979, H. Klingel pers. obs.).

During the dry season when the grass is dry, coarse and scarce, Common Hippos often feed throughout the night and even stay on for some hours in the morning before returning to the water. When during the rains food is abundant, the Common Hippos often take a rest of up to several hours in the grazing area, lying down under bushes, or they even return to the water to rest there, and then walk back to the grazing area for another helping. During the wet seasons, in the Queen Elizabeth N. P., a portion of the population emigrated from the lake-shore and settled down in wallows within the grazing areas. When the wallows dried up the animals returned to the resting places from where they had departed.

The shape of the muzzle is adapted to feeding unselectively, in a lawn-mower-like fashion. The grass is plucked with the horny lips, not with the front teeth, and torn off. The head is swung from side to side during the process. This is a rare feature, the only parallel being the White Rhino *Ceratotherium simum*. The stomach consists of four major compartments. The two anterior ones are diverticula and are fermentation chambers as is the next (third) chamber, the fourth serving for gastric digestion (Crisp 1867, Arman & Field 1973, Clemens & Malojy 1982). The first three chambers are lined with papillae, the fourth is glandular. The anatomical and functional similarities with the stomach of ruminants are obvious, and Common Hippos are often referred to as pseudo-ruminants (Arman & Field 1973, Van Hoven 1978, Eltringham 1999). Ciliate protozoa have been identified as symbionts (Van Hoven 1974). A gall bladder is present (Ganzberger & Forstenpointner 1995).

Foraging and Food Common Hippos are predominantly grazers, although isotope studies show that many Common Hippos have a significant (more than ca. 15%) browse component in their diet (Cerling *et al.* 2008). Lists of species of food plants, seasonal differences in availability and preferences are given by Field (1970a, 1972); in this study, grasses consistently taken included *Bothriochloa* sp., *Bracharia decumbens*, *Chloris gayana*, *Cynodon dactylon*, *Heteropogon contortus*, *Hyparrhenia flipendula*, *Sporobolus pyramidalis* and *Themeda triandra*. Dicotyledons are eaten accidentally where they are interspersed in the grass. In extreme situations Common Hippos feed substantially on woody plant browse (in Queen Elizabeth N. P. especially from *Cassia* sp.) and the fruit of some trees, such as the Sausage Tree *Kigelia pinnata*, are taken as well (Ansell 1965, H. Klingel pers. obs.). Aquatic vegetation is usually rare in Common Hippo waters and thus rarely taken, except locally for the Nile Cabbage *Pistia stratioides*, which, in the Queen Elizabeth N. P., is taken in small quantities during the dry seasons (Field 1970a, H. Klingel pers. obs.). In St Lucia, KwaZulu–Natal, Common Hippos eat fairly large quantities of Water Lilies

Nymphaea cerulean and the submerged macrophytes *Ruppia cirrhosa* and *Potamogeton pectinatus* (R. Taylor pers. comm.). On the plains of L. Rutanzige in Virunga N. P., DR Congo, Mugangu & Hunter (1992) found that when dry season grasses failed to yield sufficient crude protein, Common Hippos were observed to feed on aquatic vegetation.

According to a spatially explicit individual-based foraging model (Lewison & Carter 2004), Common Hippos appear to employ foraging strategies that respond to vegetation characteristics, such as vegetation quality, as well as spatial reference information, namely distance to a water source. Because of their wide, square muzzle, they feed unselectively with respect to individual plant species, but they do select the swards to a certain extent. Grazing grounds are used in an irregular pattern, and they also change with the quality and quantity of available food.

The weights of stomach contents are remarkably low and have been determined at ca. 1% (dry weight) of body weight, which is only 50% of that of other large herbivores. The stomach contains two nights' intake, and daily intake is in the order of 20 kg dry weight (Field 1970a, Arman & Field 1973, Eltringham 1999).

Where they occur in high densities, Common Hippos shape the environment. Olivier & Laurie (1974) recognize a cyclical ecosystem in which Common Hippos play the key role. The heavy grazing pressure reduces the amount of combustible material, thereby suppressing grass fires and enhancing the spreading of bushes. This in turn will lead to a reduction of grazing area and eventually to a reduction in Common Hippo numbers and density. Reduced grazing will result in higher grass growth, fires will spread, bushes and trees will be burnt and destroyed, grassland expand and Common Hippo numbers increase again. In swamps, the paths of the Common Hippos can alter the pattern of water flow, like on the banks of L. St Lucia, and thereby have an important ecological influence (R. Taylor pers. comm.). In extensive swampy areas, like the Okavango, the movements of Common Hippos create and maintain deep, clear channels through the reed-beds and permit freer movement of the water. In backswamp areas, pathways lead to the development of new channel systems during channel avulsion (McCarthy *et al.* 1998) (see also Deocampo 2002).

Exceptionally, Common Hippos have been observed to kill antelope such as Impala *Aepyceros melampus* and Common Wildebeest *Connochaetus taurinus* and livestock (e.g. La Hausse de Lalouvière & Wood 1989, Dudley 1996, 1998, Estes, in Eltringham 1999), and also to scavenge from them and even from the cadavers of conspecifics. The likely explanation is mineral deficiency in the 'normal' diet (Eltringham 1999). Licking the skin of conspecifics (R. Taylor, pers. comm.) may have the same cause. Young animals have the habit of eating dung of conspecifics; this also occurs in other ungulates and is considered to be the mechanism for transmitting intestinal symbionts. Adults are also known to feed on elephant dung, suggesting that partially digested plant material constitutes an important forage resource for Common Hippos during dry periods (Dudley 1996).

By defecating in the water Common Hippos fertilize rivers and lakes. They are thus causal for the vast harvests of fish, for example, of Lakes George and Edward in Uganda and DR Congo.

Social and Reproductive Behaviour Except where noted, the following account is based on the author's investigations from 1974 to 1979 in the Queen Elizabeth N. P., with some follow-up in the same area and in other parts of Africa, namely Mara R., Kenya;

Okavango Delta, Botswana; and Luangwa and Kafue Rivers, Zambia (Klingel 1979, 1989, 1991, H. Klingel pers. obs.). In two study areas in Queen Elizabeth N. P., more than 200 Common Hippos, the majority of the adult and subadult residents and including all key individuals, could be identified from various natural marks like scars, cuts in the ear pinna, missing ear pinnae, damaged or missing tails, colour and colour pattern. Seven Hippos were immobilized and marked with ear tags, streamers and paint, and 20 more were sprayed with paint for recognition at night.

The social organization of the Common Hippo is based on mating territoriality. Although true dominance relationships do not seem to exist in Common Hippo groups, some of the adult bulls, of the order of 10%, occupy territories in which they are dominant over all conspecifics and where they have exclusive, but not unchallenged, mating rights. Among the other group members, vague and anonymous dominance relationships roughly correlated with size can be observed, but there was no evidence for individualized dominance.

Territories extend along the shorelines of lakes and rivers in the water and include a narrow stretch of the bank. The sizes of territories vary considerably: in the Mweya Peninsula study area they measured from 250 to 500 m along the shore of L. Edward, while in the Ishasha R. study area only 50–100 m. In Ishasha, they included both banks of the river; in Mweya the outer, lake-ward boundary was not defined as there were no neighbours. In swamps, the territories were arranged in a mosaic pattern.

Bulls keep their territories for long periods of time, and they never give them up voluntarily. But occupancy is always intermittent as the bulls, like the rest of the population, emerge at night to feed. Actual tenure is considered to depend on the number of competitors, chance and physical strength. In Mweya, four of six territories were occupied by the same bulls for the whole period of observation, i.e. 4.5 years. Two of the bulls were still territorial in their original territories in September 1982, almost eight years after they were first recorded, and one of them even after 12 years. In the Ishasha study area, recorded tenure was from a few months to over two years, i.e. throughout the investigation, changes in territory boundaries, takeovers and the establishment of new territories in previously unoccupied places could be documented. From the available data, the maximum tenure can be estimated to span the whole adult life of a bull, i.e. in the order of 20–30 years.

Size of the territories, frequency of takeovers, boundary changes and length of occupancy seem to be inversely correlated with density. In Mweya, density was only 7 animals/100 m shoreline, whereas in Ishasha it was 33 animals/100 m. However, other factors are important as well. In Ishasha, some of the territorial changes were caused by changes of the course of the river, the water level and current. During the study one branch of the river fell dry and, consequently, the whole territorial set-up changed, as two out of seven bulls gave up and moved out of the area, and the others rearranged their territories. Later, during a flood, all the Common Hippos left the area. Some settled in a dead meander of the same river, others invaded a newly formed swamp, where they immediately started to establish new territories.

Territories are advertised by the bulls through their presence, their dominant behaviour and their ritualized defecation combined with urination. By rapidly wagging their tails, faeces and urine are scattered in the vicinity. This type of defecation is repeated in the

Common Hippopotamus *Hippopotamus amphibius*.

same places and results in impressive dung heaps, measuring several square metres in area. The dung heaps certainly do not function as boundary markers and they do not prevent other bulls from entering the territory, but they are thought to serve as orientation marks for the territorial individual as well as for other Common Hippos. Dung heaps are not produced by the territorial animal alone, but by virtually all passing ♂♂, and they are also found outside the territories in the grazing areas and along the inland tracks. They are rarely found in the open grassland but are regularly produced and maintained at the edges of bushes, at narrow passages between bushes, sometimes at corners of houses.

Territorial neighbours often display ritualized simultaneous defecation at their common boundary in the water. They then stand side by side a few metres apart facing in the same or opposite direction, both demonstrating strength and dominance by holding their heads high and ears forward. In this situation it is quite clear that the behaviour serves as a visual signal, as dung heaps are not produced. Smell is likely to be of importance as well.

When a territorial bull moves across the boundary of his territory, he loses his status and behaves subordinates to the territorial neighbour. Fights between territorial neighbours are generally ritualized frontal combats combined with splashing of water, which serve to demarcate boundaries. Often, the combatants hardly touch each other, advancing and retreating in response to the opponent's actions. However, serious fights occur for the possession of a territory or part of it. Then the bulls fight standing parallel facing in opposite directions and slashing with their lower canines at each other's flanks. Though the hide is several centimetres thick, these attacks can result in serious injury and even death. In these fights the combatants are

usually a territorial defender and a non-territorial challenger, but occasionally two territorial neighbours are involved if one tries to extend his territory into the other's area.

Territorial owners are extremely tolerant of all conspecifics, including adult bulls as long as these behave subordinates. Tolerance goes to the extent of the territorial bull hosting groups of 100 and more fully mature, prime bachelor bulls in the territory. In this situation the function of mating territoriality becomes absolutely clear – only the territorial individual has access to any cow in the territory.

The relations between a territorial bull and subadult bulls in his territory are of an extremely friendly nature. The subadults demonstrate their subordination in an elaborate display: on land they approach from 100 m or more away, head down, the last few paces virtually crawling on the ground, then sniffing the bull's genital region from the side or from behind without him seeming to take notice. A modified version of this behaviour is displayed in the water. Naso-nasal contacts are common. The subadult bulls often stay for hours in the immediate vicinity of the territorial bull, and there is not the slightest indication of antagonism. Rarely, during the submissive display, the territorial bull defecates on the head and back of a subadult. It is not yet clear if this is incidental or if it has a functional significance. During the day, Common Hippos live in social groups of variable size and composition (Olivier & Laurie 1974, Delvingt 1978, Klingel 1979, 1989, 1991, Karstad & Hudson 1986, Viljoen 1995). Solitary animals are generally older ♂♂ or ♀♀ about to give birth. Group size is not a sociological parameter, but rather depends on density and the environmental situation. For example, Common Hippos avoid fast currents and prefer shallow waters with sandy, open foreshores. R. Taylor (pers. comm.) measured 1.3–1.5 m as the preferred water depth for lying up during the day. In such situations the larger groups counted were over 200 animals strong, as in the Ishasha R. (Klingel 1991).

Two types of social groups can be distinguished: nursery schools consisting mainly of ♀♀ and their young, and bachelor groups consisting mainly of bulls. However, the distinction is not clear-cut, and there are often odd members of the other sex in a group. Neither of the groups is a stable social unit but both are loose associations in suitable resting places and the animals are socially but anonymously attracted to each other. Indeed, the existence of individual recognition among adults cannot be proved and it certainly does not play an important role in Common Hippo social life. However, mother and offspring do recognize each other individually, and mother–calf bonds are the only stable associations, usually lasting until the young are almost fully grown at 6–8 years of age.

In the evenings the groups break up and the animals walk singly or in mother–offspring units to their grazing areas. The latter are not monopolized or defended by an individual or group of individuals (i.e. they are not subdivided into territories). Members of a school use an exit near their resting site, or they move along the shore in the water to a place closer to the grazing grounds. They stick to a network of tracks that form through repeated use over the years. At exits the tracks can cut a metre or more into the bank, and on steep inclines tracks erode to become steep gorges that, in the Queen Elizabeth N. P., are characterized by their special plant, bird and small mammal communities. Common Hippo trails can often be recognized from a grassy, belly-smoothed strip in the middle. Regular paths are also used in shallow lakes.

After their nocturnal feeding trips the animals return preferentially to the sites from which they have departed the previous evening, resulting in a certain constancy of group composition. But each individual has, independently of the group, its own home-range and several resting places. In one study area, Mweya Peninsula, the majority of the known animals were located for years in the same day home-ranges of 100–200 m in length. Home-ranges do not coincide with the territories, nor are they restricted to a particular territory. Depending on territory size, a ♀ can be at home in one or in several territories. Changes in group composition also occur during the day. Frequency depends on the spacing of the groups but also on other factors. Some individuals were particularly mobile and, possibly out of curiosity about the observer, their movements were correlated with his, and they moved parallel to the shore in the water, crossing territories and passing groups of conspecifics without any sign of antagonism and without any attempts by the bulls to prevent their departure.

Generally, Common Hippos are quite philopatric and stay within their regular home-ranges. In Queen Elizabeth N. P., a portion of the residents, especially non-territorial ♂♂, used to settle in wet-season pools, utilizing the grazing area nearby. At the beginning of the dry season they would return to where they had come from. When their rivers and wallows dry up, they are eventually forced to move, occasionally over large distances, to find suitable water bodies.

Matings take place exclusively in the aquatic part of territories. Accordingly, for the ♂, the possession of a territory is an absolute prerequisite for reproduction, although it is by no means a guarantee. Some bulls maintained territories in areas that were unattractive to ♀♀ and they probably had no access to cows. However, in the Ishasha R. several 'bad' territories changed to 'good' ones when the course of the river and the water level changed and consequently some ♀♀ moved in. Other territories changed for the worse. It is therefore a better strategy for a bull to occupy a bad territory than to be a non-territorial bachelor.

Oestrus lasts for 2–3 days and up to six copulations occur per day. Although the ♀♀ tend to return in the morning to the place and thus to the territory from which they had departed the previous night, they are promiscuous and likely to visit two or more territories in succession and mate with the respective owners.

A few days before giving birth to a single young, the cows separate from the group. When the cow is undisturbed, birth is in shallow water at the waterline; when she is disturbed, birth can take place in deeper water. The young are precocious and within a few minutes after birth able to suck even under water and to follow their mothers into deeper water. Eltringham (1999) suggested that milk is injected into the calf's mouth by muscular action on the part of the mother, as occurs in some cetaceans. However, young use their tongue and mouth roof around their mothers' nipple while actively sucking, but not the lips, which are inflexible (Kingdon 1979).

Mother and infant stay away from conspecifics and prefer to rest in close proximity at the edge of the water, the mother obviously without eating for several days. For about ten days she is intolerant of all conspecifics and attacks even the territorial bull and her own elder offspring should they approach. This behaviour, which is also observed in other ungulates, is considered to prevent false imprinting. It also serves to protect the infant from attacks by conspecifics. After this period, the mother will graze on the bank during the day with

the infant resting nearby. After several weeks mother and calf will walk, at night, to the grazing grounds where the infant will be parked under a bush whilst the mother feeds. She eventually returns, collects the calf and they return to the water together. Occasionally, calves aged 6–12 months stay behind in a crèche near the water whilst their mothers depart on their nocturnal foraging excursions. The birth of a sibling does not disrupt existing bonds, and ♀♀ with several young, up to three, of different ages, can be observed. The marching order is by age, the youngest first, directly behind the mother.

Numerous cases of infanticide have been reported, some directly observed, others based on circumstantial evidence, and are attributed to ♂♂. However, in a recently filmed episode the infanticidal individual was clearly a subadult, of undetermined sex (M. Deeble & V. Stone pers. comm.). Verheyen (1954) considered adult ♂♂ to be the major enemies of infants. Lewison (1998) analysed the evidence and concluded that infanticide in Common Hippos, as has been demonstrated for Lions, may be a reproductive strategy by which a new territorial ♂ kills his predecessor's offspring to shorten the inter-birth intervals of the ♀ and thus enhance the male's reproductive success. However, the evidence is only circumstantial. In none of the cases was a change of territorial ownership and/or the status of the infanticidal individual observed. As all or most incidents occurred in the dry season, high densities and nutritional stress may have triggered the behaviour.

Common Hippos command a rich repertoire of signals and means of communication, the actual significance of which is only partly understood. The impressive gape signals strength and presence; it is, however, very similar to the yawn, which is of shorter duration, and conspecifics do not seem to be impressed by either. Also, the yawn/gape is displayed by all members of a group including infants, and it occurs with highest frequency just before they go on land in the evenings – suggesting that the yawn/gape may be an expression of excitement, and not a threat (Kingdon 1979, H. Klingel pers. obs.). When attacking, Common Hippos have their mouth only partly open, and this is clearly a threat that is understood by conspecifics. Head up signals dominance, head low, lip smacking and tail wagging with or without defecation are signals of submission, occurring in minor confrontations and by the ♀ during pre-mating activities (Karstad & Hudson 1986, H. Klingel pers. obs.). Behaviour analogous to 'flehmen' has only recently been observed to occur in Common Hippos and probably has no communicative value (Zapico 1999).

Several vocalizations can be distinguished, but interpretations of their significance are still largely speculative. The most common consists of a series of guttural honks preceded and followed by a high-pitched squeal. It is contagious, being started by one individual, repeated by others, and within seconds all members of a group, and soon the neighbours as well join in a cacophony that carries over several kilometres. Calls are individually different and may serve for individual recognition. Sometimes mother and young call and answer after having lost contact while on their walk to the grazing grounds. Other individuals occasionally utter this call at any time of day or night, and they sometimes get answers from far away, but often not (H. Klingel pers. obs.). When fighting and in distress, Common Hippos produce long high-pitched squeals. Barklow (1997) recorded and analysed three types of underwater sounds that are rarely audible on the surface: a whine signalling submission; a croak used by young; and clicks for communication (and see Barklow 2004). When facing

each other they often make a low-pitched loud rumbling noise (R. Taylor pers. comm.).

Many bird species, especially waders, use Common Hippos for perching; some run up and down the animals' backs hunting insects and ticks (e.g. African Jacanas *Actophilornis africanus*), others catch insects that the Common Hippo has disturbed in the water vegetation (see Eltringham 1999 for summary). Hediger (1951) described a case of mutualism between Common Hippos and the Cleaner Fish *Labeo velifer*. M. Deeble & V. Stone (pers. comm.) have observed and recorded on film that Common Hippos actually invite the fish to clean any area of the body, including the mouth cavity, and that they visit cleaning stations where the fish are waiting. Erwee (1996) observed a Common Hippo saving an Impala *Aepyceros melampus* from drowning, by pushing it 'carefully' onto dry land, and there are other instances of Common Hippos displaying similar behaviour, including intervening in attacks on Impalas and other antelopes by crocodiles or large predators.

Common Hippos are said to be responsible for more human deaths than any or even all other dangerous wildlife species combined. The truth is difficult to assess as there are no reliable statistics. Common Hippos are certainly dangerous, especially when cornered and wounded or provoked. Most of the casualties are of fishermen who fatalistically drive their boats right through the Common Hippo schools, oblivious to the danger. If the boats are attacked the fishermen will jump out, or may fall into the water, and drown because they generally cannot swim; they may also get bitten by the Hippos and may lose a limb or a life. On land, dangerous situations for humans arise when bumping into a Common Hippo, especially at night, and when inadvertently getting between a mother and her young. Normally, the relations between Common Hippos and people are quite relaxed, with animals idling in the water within as near as 20 m of people bathing or washing their clothes (H. Klingel pers. obs.).

In much of their range crop-raiding by Common Hippos is a big problem. Chain-link fencing is typically ineffective at excluding crop-raiders, especially where it cuts across well-used tracks, because the animals simply trample the fences. Likewise, single strands of electrical wire are only partly effective, as some of the animals, upon contact, rush forward and break the wire. One solution involves constructing a simple barrier like a wooden rail or a shallow ditch about 50 cm in front of and parallel to the electric wire. Both obstacles help slow the animal's pace, thereby serving as a warning before the animal touches the high voltage wire. In KwaZulu-Natal, fields are successfully protected by 1.2–1.5 m deep trenches (R. Taylor pers. comm.).

Reproduction and Population Structure Detailed information on breeding and population structure is available from culling schemes, in particular from Queen Elizabeth N. P. (Laws & Clough 1966), the Luangwa R. in E Zambia (Sayer & Rakha 1974, Marshall & Sayer 1976) and South Africa's Kruger N. P. (Smuts & Whyte 1981). Average age of sexual maturity in ♂♂ (based on testes weights) is 7–8 years (Laws & Clough 1966, Sayer & Rakha 1974, Smuts & Whyte 1981), although spermatogenesis may begin much earlier (as early as two years of age in animals from Kruger; Smuts & Whyte 1981). Based on follicular size, ♀♀ reach sexual maturity at about seven years, although some ♀♀ examined have been found to be sexually mature at much younger ages, including one at three years in Uganda (Laws & Clough 1966, Sayer & Rakha 1974). The age

female

male

Common Hippopotamus *Hippopotamus amphibius*.

at which all ♀♀ are pregnant varies between the three regions in which major studies on reproduction have been conducted: 11 years in Kruger, but 20 years in Uganda and Zambia, indicating different degrees of crowding and nutritional stress (Eltringham 1999). Captive animals may breed at an earlier age, and Dittrich (1976) recorded one ♀ conceiving at only 2 years and 3.5 months. Males are sexually active throughout life, their body weight continuing to increase and testis continuing to grow.

Births are recorded any time of the year; however, there is pronounced seasonality, and most births in Uganda (close to the equator) occur during the rains (Laws & Clough 1966). In Zambia, conceptions occurred throughout the year, but births only during the wet season (Marshall & Sayer 1976). Gestation lasts for about 240 days, and usually a single calf, weighing a mere 50 kg, is born (Laws & Clough 1966, Smuts & Whyte 1981, Eltringham 1999). Twins occur infrequently; in the sample of 276 culled specimens examined by Laws & Clough (1966), twins were recorded twice.

Calving intervals are 2–3 years (see Smuts & Whyte 1981), and oestrous cycle is given as around 50 days (Laws & Clough 1966, Smuts & Whyte 1981, Eltringham 1999). There is some evidence of a postpartum oestrus, as 25% of ♀♀ examined by Laws & Clough (1966) were both pregnant and lactating. Conception rates were close to 40% in Kruger N. P. (Smuts & Whyte 1981) and 27% in Queen Elizabeth N. P. (Laws & Clough 1966). Percentage of lactating ♀♀ in Uganda was almost 60% (Laws & Clough 1966), and 78% in South Africa (Smuts & Whyte 1981). Weaning probably takes place between six and eight months, with most calves weaned by 12 (Eltringham 1999); however, calves as young as six to eight weeks often have considerable quantities of grass in the stomach (Laws & Clough 1966).

Sex ratio is 1 : 1 in foetuses (Bere 1959, Laws & Clough 1966, Smuts & Whyte 1981), infants and young (H. Klingel pers. obs.). Reported adult sex ratios are likely to be inaccurate due to the segregation of sexes. Smuts & Whyte (1981) reported a ratio of 1 : 1.93 in Kruger N. P. (n = 463), while Marshall & Sayer (1976) recorded 1 : 0.98 in 1970

($n = 375$) and 1 : 1.56 in 1971 in Zambia ($n = 210$), the difference in the proportion of ♂♂ due to a greater effort during 1970 to take a more random sample. Laws & Clough (1966) found a nearly exact sex ratio in Uganda, and confirmed that there was a skewed distribution of sexes according to habitat: in small wallows, 313 ♂♂ and 110 ♀♀, and on lake shores, 600 ♀♀ and 821 ♂♂. Population structures of Common Hippos from culling operations exist (e.g. Marshall & Sayer 1976), although samples are biased given the tendency for younger animals not to be culled (and see Eltringham 1999).

Longevity is recorded at 61 years in captivity (Wiesner & von den Driesch 1996).

Common Hippopotamus *Hippopotamus amphibius* juvenile mouth showing adaptation of tongue and upper lip to suck maternal nipple.

Predators, Parasites and Diseases Lions *Panthera leo* succeed occasionally in bringing down an adult Hippo, but they have no impact on the population. Also, young animals are preyed upon by Spotted Hyaenas *Crocuta crocuta* and Lions (Kingdon 1979). In one attack by five hyaenas on an infant, at night, the cow's defence was quite inadequate: she repeatedly chased individual hyaenas that came close, but in the process she again and again left the calf unprotected. The hyaenas took turns in attacking the calf and fleeing from the mother and they eventually managed to bring the calf down. The mother stood for several hours over the body and protected it from being eaten, with the hyaenas sitting nearby. Eventually, after dawn, the mother walked the short distance to the water and the hyaenas had their meal (H. Klingel pers. obs.). Nile Crocodiles *Crocodilus niloticus* are potential predators of Common Hippos, especially young ones, but no records are known. Most observers report Common Hippos to be dominant to crocodiles (see Kofron 1993).

In the wild, Common Hippos are susceptible to rinderpest, a viral disease that was introduced to Africa towards the end of the nineteenth century and which decimated large numbers of domestic and wild ungulates. It is not known if Common Hippos actually succumbed to the disease in any numbers, but they developed antibodies (Plowright *et al.* 1964). Laws (1968) correlated the presence of rinderpest antibodies in culled Common Hippos with

dated outbreaks of the disease and could thereby construct an ageing scale based on tooth eruption and wear, which is one of the most accurate for any wild animal species.

A major and often deadly disease of Common Hippos is anthrax, caused by *Bacillus anthracis*. Outbreaks have been reported repeatedly from Uganda and Congo/DR Congo during the past 40 years, though they were not necessarily diagnosed correctly. One identified outbreak, in 1978, resulted in high mortality in some areas of Queen Elizabeth N. P., but had little impact on the population as a whole (H. Klingel pers. obs.). An outbreak in Zambia in 1987 resulted in the death of >4000 Common Hippos out of a population of 20,000 (Turnbull *et al.* 1991). In 2004, anthrax outbreaks were reported from Zambia and Uganda, the latter claiming about 300 Common Hippos (C. Tumwesigye pers. comm.). Other disease organisms afflicting Common Hippos are *Brucella abortus* (which causes brucellosis) and several species of *Salmonella* and *Trypanosoma*.

Major parasites include flatworms (liver flukes *Fasciola nyansae* are found in the livers of most Common Hippos, while one species of blood fluke, *Schistosoma hippopotami*, is host-specific), nematodes, and ectoparasites, including ticks and a fluke *Oculotrema hippopotami* that lives on the outer surface of the eye (see Du Preez & Moeng 2004). See Eltringham (1999) for an overview.

Conservation IUCN Category: Vulnerable A4cd. CITES: Appendix II.

Today Common Hippos are present in numerous protected areas across the continent, with important populations in Niokolo-Koba N. P. (Senegal), National Park of Upper Niger (Guinea), Comoé N. P. (Côte d'Ivoire), W. N. P./Arly/Pendjari (Benin, Niger, Burkina Faso), Zakouma N. P. (Chad), Queen Elizabeth and Murchison Falls National Parks (Uganda), Salonga, Upemba and Virunga National Parks (DR Congo), Serengeti, Ruaha, Mikumi and Tarangire National Parks, Ngorongoro Crater Conservation Area and Selous G. R. (Tanzania), Amboseli, Lake Nakuru and Tsavo National Parks and Masai Mara and Samburu National Reserves (Kenya), Kasanka, Kafue, North and South Luangwa and Lower Zambezi National Parks (Zambia), Kasungu and Lake Malawi National Parks (Malawi), Hwange and Mana Pools National Parks (Zimbabwe), Chobe N. P. (Botswana), Gorongosa N. P. and Niassa G. R. (Mozambique) and Kruger N. P. (South Africa).

However, across their range, and in particular in West Africa, many populations of Common Hippos are decreasing due to droughts, poaching and to habitat loss and habitat fragmentation from changing land use and damming of rivers (Eltringham 1993a, 1999, Lewison 2007, Zisadza *et al.* 2010). Two very large Common Hippo populations suffered particularly heavy losses through intense commercial poaching by military and civilian poachers. In Uganda, Common Hippos of Queen Elizabeth N. P. declined during the war and unrest of the late 1970s to 1980s from about 20,000 to 2000 (Eltringham 1999). Since then, an increase to only 2600 in 2004 has been recorded (C. Tumwesigye pers. comm.). More recently, in DR Congo, an even more dramatic decline has been reported from the Virunga N. P. population, which, during the recent civil war and turmoil, declined by about 97%, from close to 30,000 in the 1970s (Delvingt 1978) to 1300 in 2003 (A. Plumtre pers. comm.) and to perhaps less than 400 in 2006 (Lewison 2006). Hunting pressure is presently mostly for meat; however, there is increasing demand for tusks, the ivory of which is said to be softer and easier to carve than elephant ivory.

Common Hippopotamus *Hippopotamus amphibius* seated.

An important conservation measure is the translocation of Common Hippos, although immobilization of animals, for research and/or for translocation, poses problems. It has to be done at night in the grazing grounds, to make certain that the drugged animal does not reach deep water and drown. Also, no safe drug combination has been

developed, and the responses of the animals are highly variable (H. Klingel pers. obs.). M. Woodford (pers. comm.) has suggested that the parasite load of the animal might be responsible for the inconsistent effects. In South Africa, Common Hippos are captured by pushing them into a funnel leading directly onto a lorry (R. Taylor pers. comm.). Kingdon (1997) sees much potential in Common Hippos being domesticated as a meat source. The dung also could be made use of in fish farms, thereby producing additional protein.

Measurements

Hippopotamus amphibius

HB (♂ ♂): 3120 (2600–3500) mm, n = 54

HB (♀ ♀): 2990 (2590–3370) mm, n = 156

Sh. ht (♂ ♂): 1500 (1290–1720) mm, n = 32

Sh. ht (♀ ♀): 1440 (1100–1580) mm, n = 36

WT (♂ ♂): 1546 (955–1999) kg, n = 86

WT (♀ ♀): 1385 (995–1850) kg, n = 192

Kruger N. P. (Pienaar *et al.* 1966, I. Whyte, pers. comm.)

Laws (1963, in Eltringham 1999), in Uganda, found the average weight to be 1536 kg for ♂ ♂, with a maximum of 2065 kg, and 1386 kg for ♀ ♀, with a maximum of 1716 kg. Ledger (1968) reported an average of 1490 kg (range 1179–1714 kg, n = 4) for ♂ ♂, and 1277 kg (range 1185–1401 kg, n = 4) for ♀ ♀. Based on the samples of 189 ♂ ♂ and 186 ♀ ♀ in the Luangwa Valley, ♀ ♀ appear to approach an asymptotic weight at around 24 years of age, while ♂ ♂ continue to grow throughout life (Marshall & Sayer 1976). The record tusk length is 1638 mm for animal from Congo (Rowland Ward).

Hans Klingel

GENUS *Choeropsis* Pygmy Hippopotamus

Choeropsis Leidy, 1852. J. Acad. Nat. Sci., Philadelphia 2 (1): 207.

There is only one living species of *Choeropsis*, the 'Pygmy' or Liberian Hippopotamus, *C. liberiensis*. It is now restricted to lowland forests of Côte d'Ivoire, Sierra Leone, Liberia and Guinea, but in the recent past, it probably also populated coastal regions east of these countries as far as the Niger Delta. The Pygmy Hippopotamus (hereafter Pygmy Hippo) is similar in appearance to the well-known Common Hippopotamus *Hippopotamus amphibius*, but it is much smaller than the latter, its back slopes forward, and its eyes, ears and nostrils are situated lower down on the cranium. Its general proportions are also different, with relatively longer limbs and a proportionately smaller, narrower head. Osteologically, it differs by its sagittal crest sloping backward, its lachrymal separated from the nasal by an anterior extension of the frontal, its low-crowned cheekteeth and the presence of only two incisors on the mandible.

Fossils of actual pygmy hippopotamids are known from several islands, including Cyprus, Malta, Crete and Madagascar. Continental

small hippos were discovered in the Neogene of eastern Africa: *Hexaprotodon ? imagunculus* in the western branch of the Great Rift Valley; aff. *Hippopotamus aethiopicus* and *Archaeopotamus lothagamensis* in the eastern branch. For those continental species, small size probably permitted the use of ecological niches unsuitable for the abundant and much larger species found in the same deposits. In the case of *Choeropsis*, small size could, in fact, be a primitive condition (the oldest known hippos being about the same size or somewhat smaller) and/or could be an adaptation to its habitat, unusual for a hippopotamid. Indeed, very large size is not particularly beneficial for moving through dense forest vegetation and must be sustained by an abundant, nutritious and reliable food supply. Many peculiar traits of *Choeropsis* can in fact be interpreted similarly: its forward sloping back perhaps facilitates passage through dense vegetation, whereas in these conditions low orbits could offer better protection for the eyes. Furthermore, much of this vegetation is woody and

Pygmy Hippopotamus *Choeropsis liberiensis*.

not especially nutritious. *Choeropsis* shows the same sun-sensitive skin histology as *Hippopotamus*, but can venture outside water more frequently in its shady and humid environment, and is less aquatic than its larger extant relative.

The Pygmy Hippo was initially classified in the genus *Hippopotamus* by Morton (1844), then in its own genus (Leidy 1852). In 1977, on the basis of separation between the lachrymal and nasal bones, Coryndon (1977) merged *Choeropsis* into the genus *Hexaprotodon* including most fossil species. However, this morphology was shown to be primitive in the family (Harris 1991a), whereas Harrison (1997) favoured generic distinction of the Pygmy Hippo because of its peculiar overall anatomy. Accordingly, a recent review of the taxonomy and phylogeny of the hippopotamids has restricted the definition of *Hexaprotodon* and thus revalidated *Choeropsis* for the extant Pygmy Hippo (Boissarie 2005).

Choeropsis has no known fossil record; its mosaic of primitive (e.g. low sagittal crest), derived (i.e. number of incisors) and unique (i.e. strong nasal spine of the palatine bone) characters among Hippopotamidae suggests that its ancestors separated from other lineages in the late Miocene (Harrison 1997, Boissarie 2005). At this time, hippopotamids underwent a limited radiation, becoming for the first time abundant and diversified in African ecosystems.

At least four main lineages emerged, including *Choeropsis* (Boissarie 2005). Among the three others, the first is recognized in eastern Africa and the Arabian Peninsula as genus *Archaeopotamus*. Its species exhibited an elongated, shallow and narrow mandibular symphysis (Coryndon 1977, Gentry 1999, Weston 2000). The second lineage, the extinct genus *Hexaprotodon*, was seemingly rare in Africa, but flourished in southern Asia, from India to Indonesia, and maybe in southern Europe. Its species were characterized by a robust, high and moderately wide mandibular symphysis. The third lineage, represented by the monospecific *Saotherium* from basal Pliocene in central Africa, has some affinities with *Choeropsis*. Both genera share an elongated braincase rounded in transverse section and relatively large orbits. These characters could be primitive, so may not express actual close phylogenetic relationships. In fact, the relationships between all these lineages – thus, the origin of *Choeropsis* – are still unclear. In any case, *Choeropsis* and *Saotherium* suggest a long and diverse hippopotamid evolutionary history in central and western Africa, despite a fossil record far more sparse than in the eastern part of the continent.

Jean-Renaud Boissarie & S. Keith Eltringham

Choeropsis liberiensis PYGMY HIPPOPOTAMUS

Fr. Hippopotame nain, Hippopotame pygmée; Ger. Zwergflusspferd

Choeropsis liberiensis (Morton, 1849). J. Acad. Nat. Sci., Philadelphia 2 (1): 232. St Paul's River, Liberia.Pygmy Hippopotamus *Choeropsis liberiensis*.*Choeropsis liberiensis*

Taxonomy Two subspecies are recognized. The form *C. l. heslopi*, from the Niger Delta, is originally known from three skulls, one specimen shot by Heslop himself and two skulls obtained from hunters (Heslop 1945); a further two skulls were collected by J. B. I. Mackay in 1928 (Ritchie 1930). It was considered a distinct subspecies by Corbet (1969) and Coryndon (1977), based on variations in cranial anatomy. Synonyms: *heslopi*, *minor*. Chromosome number: $2n = 36$ (K. Benirschke pers. comm.).

Description A secretive, nocturnal, highly solitary, pig-like quadruped resembling, but significantly differing in size, anatomy, behaviour and ecology from, the Common Hippopotamus *Hippopotamus amphibius* (see Similar Species). Overall colouration ranges from grey-brown to purplish-black with creamy-brown underparts. The body profile is raked; the legs less massive than the Common Hippo and the digits are more free and mobile. Nostrils and diminutive ears can be closed by muscular valves, as in *Hippopotamus*.

The dental formula is $I^2/_1, C^1/_1, P^3/_3, M^3/_3 = 34$, which is reduced from the ancestral condition of 44. The incisors are peg-like and the canine teeth, which are used for defence and aggression rather than for feeding, are sharpened by occlusal wear and are open-rooted and continuously growing. The molariform teeth are low-crowned with a grinding function.

Geographic Variation

C. l. liberiensis: Upper Guinean lowland forests, in Guinea, Sierra Leone, Liberia and Côte d'Ivoire.

C. l. heslopi (Heslop's Pygmy Hippo): Niger Delta. Probably extinct. The Nigerian subspecies has been described as having a more horizontal dorsal profile, as contrasted with the more sloped profile characteristic of the nominate subspecies (I. R. P. Heslop pers. comm.); also differs in cranial features (discussed by Corbet 1969).

Similar Species

Hippopotamus amphibius. Largely allopatric, although their ranges overlap in the upper stretches of some rivers in Côte d'Ivoire (see Roth *et al.* 1996, 2004) and perhaps in NW Sierra Leone (Grubb *et al.* 1998). Larger overall size, but with proportionally shorter limbs; nostrils and bony orbits more prominent; toes close-knit; two pairs of lower incisors. Typically solitary or in small groups, and confined to forested regions close to rivers. For a comparative review of *Choeropsis* and *Hippopotamus* see Eltringham (1999).

Distribution Endemic to Africa, where currently confined to the Upper Guinean lowland forests of Liberia, Côte d'Ivoire, Guinea and Sierra Leone. An isolated subspecies, *C. l. heslopi*, formerly occurred some 1800 km to the east, from the Niger Delta east to the Cross R. in Nigeria (Heslop 1945; and see Corbet 1969, Ansell 1972). Reports of this subspecies in the 1930s and 1940s were from the swamps of the Cross R. region of Calabar Province, and from swamps of the Niger R. and its tributaries in the British colonial administrative divisions of Kwale, Asaba, Onitsha and Aboada. The subspecies has not been reliably recorded in more than half a century, and its continued presence seems unlikely. Powell (1995) suggested that the only remaining possibility was in the Upper Orashi Forest Reserve.

Their current distribution is more fragmented than in the past, largely due to the extensive forest loss that has taken place in the lowland rainforests of Upper Guinea. The core of the species' range is centred on Liberia, which has the most extensive tracts of intact lowland forest in the region (Christie *et al.* 2007). Pygmy Hippos are also present in neighbouring E Sierra Leone (in the Gola Forest

region), SE Guinea (including Ziama and Diécké) and SW Côte d'Ivoire (Eltringham 1993b, 1999, Grubb *et al.* 1998, Roth *et al.* 2004, Mallon *et al.* 2011).

In Côte d'Ivoire, the most northerly occurrence of the Pygmy Hippo is between 7° 20'N and 7° 30'N in the Upper Cavally R. valley, just south of the Guinean border, and along the Upper Boan R., south of the Mt Nimba massif (Roth *et al.* 1996, 2004). They have been recorded from Azagny N. P. and along the Bandama R. in SE Côte d'Ivoire, just west of Abidjan (Roth *et al.* 1996, 2004), which is about the farthest east the nominate form has been recorded (4° 18'W). In Liberia, their distribution seems to be divided between the large remaining forest blocks in the south-east (centred on Sapo N. P.) and north-west of the country (Mallon *et al.* 2011). The farthest west the species appears to have been authentically recorded in the past is near Forécariah, in Kindia, Guinea (Dekeyser 1955; see Grubb *et al.* 1998), but there are no present-day records from further west than NW Sierra Leone (Grubb *et al.* 1998) where it is possible they may survive in Outamba-Kilimi N. P. in sympatry with the Common Hippo. Pygmy Hippos are also still recorded from the Loma Mts in the north of the country.

Except for the reports from NW Sierra Leone (Grubb *et al.* 1998) and Côte d'Ivoire by Roth *et al.* (1996, 2004) and Hentschel (1990), such as on the Bandama R. as far north as the confluence of the Nzi R., no other locations have been verified where the ranges of Pygmy and Common Hippos currently overlap. Historically, however, it is likely that these two species did have small range overlaps; for example, in SW Liberia in the 1930s (Van Ness Allen 1939) and 100 years ago in the Junk River region in Liberia (Schomburgk 1912, 1913, 1922). Heslop (1945) reported seeing Pygmy Hippopotamus tracks within 20 feet of those of a Common Hippopotamus in the Niger Delta region.

Records of the species from Gambia and Ghana were rejected by Grubb *et al.* (1998), while another isolated record from Guinea-Bissau (Cristino & Melo 1958) almost certainly refers to the Common Hippo.

Habitat Lowland primary and secondary evergreen forests, sometimes penetrating savanna regions along gallery forests. Prefers isolated areas with low human disturbance; riverine and swamp areas are frequented much more than upland forest sites. The habitat must offer suitable cover for resting, calving and nursing of calves. Pygmy Hippos often follow water-courses and dry-season forest gullies in their travels and do not hesitate to cross rivers and streams, usually fleeing water to seek refuge in the forest when encountered. Under-cut and eroded banks of forest streams and rivers are not uncommonly used as opportunistic retreats, a habit that is exploited by hunters (Schomburgk 1913, Robinson 1981); the latter author provides a detailed description of one such denning structure in Liberia. Seasonal climate within the species' range is characterized by a major dry season occurring variably between Nov and Mar, with significant rainfall during the balance of the year.

Abundance The total size of the wild population is unknown, but was estimated in the thousands in the early 1990s with the bulk of the population in Liberia, and perhaps less than 100 animals in Sierra Leone (Eltringham 1993b, 1999). However, Roth *et al.* (1996, 2004) present evidence (see below) contradicting the traditional view that Liberia remains the only stronghold for this species. Using faecal

Lateral, dorsal and palatal views of skull of Pygmy Hippopotamus *Choeropsis liberiensis*.

droppings and a decay rate method, Hentschel (1990) estimated mean population densities in Tai N. P., Côte d'Ivoire at 3.6 ind/km² in primary forest and 2.9 ind/km² in secondary forest. Based on these density estimates, Hentschel (1990) estimated a total population of about 14,200 Pygmy Hippos in Tai N. P. and its surrounding areas, although Roth *et al.* (2004) caution that this was probably an overestimate. Subsequently, recent studies in the eastern part of Tai N. P. have revealed that densities decreased to 0.3 ind/km² in 1998 and to 0.2 ind/km² in 2001. Densities in the interior and in the western part of the park ranged from 0.8 ind/km² in 1995 to 1.4 ind/km² in 1998. In the northern adjacent N'zo G. R., densities of up to 2.5 ind/km² existed in 1998. From 1999 to 2001 the Hippo population there increased to 4.1 ind/km² (Roth *et al.* 2004). The latter authors concluded that the total number of Pygmy Hippos in Tai N. P. and its adjacent forest areas was certainly less than 10,000 animals, and estimated the total number in Côte d'Ivoire as probably no more than 15,000 in total. Notwithstanding errors associated with extrapolating population density estimates from dung pellet counts, these figures suggest that the total population of Pygmy Hippos is probably larger than that indicated by Eltringham (1993b, 1999).

Adaptations Compared with the Common Hippo, the Pygmy Hippo is more adapted to terrestrial locomotion. The toes of the feet are less webbed than the Common Hippo, and better suited to frequent movement in and out of rivers and streams and forest travel (Robinson 1970). Ocular orbits are less prominent, consistent with a less aquatic existence. The body profile slopes from the rear to fore facilitating movement through riparian vegetation. As in the Common Hippo, the skin is well lubricated with mucus-like droplets

LEFT: Sketch of neonate.

ABOVE: Pygmy Hippopotamus *Chroeropsis liberiensis* myology of head.

exuding from pores that cover the body. The secretions may take on the appearance of a foamy film over the body surface when rubbed against vegetation.

The digestive system is characterized by a four-chambered stomach (microbial fermentation probably taking place in the first three chambers), lacks a caecum and, like the Common Hippo, has simple small and large intestines (Macdonald & Hartman 1983). They are classified as pseudo-ruminants, as they do not regurgitate and chew their food. Newborn individuals have a lactational groove that diverts milk directly into the glandular portion of the stomach, resembling the same functional morphology found in ruminants (A.A. Macdonald & W. Hartman pers. comm.).

Pygmy Hippos are primarily, albeit not exclusively, nocturnal and crepuscular, spending the daylight hours resting (Robinson 1970, Bülow 1988); evidence from camera traps shows that they may be active throughout the night and also during the day (Mallon *et al.* 2011).

Foraging and Food Pygmy Hippos consume a wide variety of herbaceous materials (forbs, sedges, ferns and fallen fruit), as reported by Hentschel (1990) and Robinson (1970, 1971, 2003). Hentschel (1990) concluded that the feeding spectrum is wide and consists mainly of herbs and fruits. His feeding experiments, direct observations and examinations of damage at feeding sites showed the use, as food, of 17 ferns, 26 dicotyledonous plants, 16 monocotyledons and the fruits of 24 tree species. Feeding preferences varied per individual and some ferns and monocots were readily eaten by all captured animals. The most preferred food plants had high sodium content. Captive diets frequently consist of green leafy vegetables, lucerne, grass hays, carrots, apples, oats, bread and supplements of trace minerals and alpha tocopherol. Robinson (2003) consistently found that a small, recumbent, vine-like forb, widely known as 'Deewinkon' (*Geophila* sp.), is a preferred food throughout Liberia. They do not appear to eat aquatic vegetation or animal matter in the wild. Heaped dung and tail-splattered excrement are commonly found along trailside vegetation. They very occasionally consume crops during wet seasons in remote agricultural areas, but are not regarded as a crop pest. They have been observed standing on their hindlegs (with their front legs against the stem) to reach ferns growing within *Raphia* palms (Bülow 1988).

Social and Reproductive Behaviour Pygmy Hippos are extremely difficult to observe, and even in primary forest areas of low human population density, they are rarely seen. It has been rarely photographed, even with the recent advent of camera-trap technology (e.g. see Collen *et al.* 2011). Consequently, the behaviour of this species in the wild is poorly known, and detailed information is lacking on home-range, territoriality, sexual behaviour and maternal–young interactions. They are known to be highly solitary, and maximum group size reported is three, when a ♀, ♂ and a juvenile offspring may keep transient company while breeding (Robinson 1970). When frightened, they seek forest or rivers for escape from intruders, and are formidable at close quarters if injured or trapped. Considerable time is spent travelling/foraging along meandering, tunnel-like paths that they create in streamside vegetation and through forests and swamps (Robinson 1970).

Hentschel (1990) recorded a home-range size of 50 ha for a radio-collared ♀, and a daily range of 1.8 ha; Bülow (1988) recorded a home range of 180 ha for a ♂. Home-ranges of several female Pygmy Hippos may overlap, and they appear to be very residential. Home-ranges seem to depend on the presence of small streams with submerged trees, root hollows, swampy depressions, and size and density of ground vegetation, rather than nutritional factors or proximity of rivers (Roth *et al.* 2004).

In captivity, copulation has been observed on land and in water. However, parturition, contrary to the Common Hippo, is confined to land. Unlike the Common Hippo, young calves in captivity are not in the constant company of their mothers, but remain in seclusion and suckle intermittently (Galat-Luong 1981). This explains why tracks of young animals are hardly ever found (Hentschel 1990), because young start following their mothers at around 3–5 months of age when they are already quite large.

Reproduction and Population Structure No distinct parturition season has been observed in captivity or in the wild, although some hunters report that newborn animals are observed more commonly in the early dry season between Nov and Jan (Robinson 1970). Oestrous cycle is about 35 days, with oestrus lasting one to two days (Tobler 1988). Gestation period is reported to be 6–7 months in captivity (Zschokke & Steck 2001). They have an

epitheliochorial placenta (K. Benirschke, pers. comm.). A single young is born out of the water with a birth-weight of 4.5–6.2 kg; twinning does occur, but is rare (less than 1% of pregnancies in captivity result in the birth of twins; Hlavacek *et al.* 2005). Weaning occurs at 6–8 months. Reproductive maturity is reported to be 3–5 years (Lang 1975); in captivity, the youngest ♀ to give birth was 2 years 10 months, and the youngest ♂ to mate, 3 years 4 months (Hlavacek *et al.* 2005). Captive adult body size is achieved by three years. Maximum age in captivity is in the order of 35–40 years; one wild-caught captive ♀ lived to nearly 44 years of age (A. Conway pers. comm.). While no data exist for wild animals, it is expected to be substantially less. Bülow (1988) recorded an instance in which a young Pygmy Hippo died as a result of drowning in the Azagny N. P., indicative that swampy areas such as the *Raphia* swamps in Azagny are not optimal for reproduction because young are not accomplished swimmers.

Zschokke (2002) noted that the total captive population of the Pygmy Hippo at the time had a highly female-biased sex ratio at birth (41% ♂♂), exceeding most other known distorted sex ratios in captive mammals. This deviation was not compensated for by a higher juvenile mortality in ♀♀, but seemed to be related to high feeding intensity and ‘hands-on’ husbandry that favoured production of daughters.

Predators, Parasites and Diseases The main predators, particularly for young, are Leopards *Panthera pardus*, Nile Crocodiles *Crocodylus niloticus* and African Rock Pythons *Python sebae*. Hentschel (1990) obtained a photograph of a juvenile Pygmy Hippo killed by a Leopard. Disease in wild animals is undocumented. In captivity, they are relatively hardy with competent husbandry, and most health problems relate to husbandry shortfalls. The author is aware of several cases of dental malocclusion (and see Johnston 2002) and solar dermatitis resulting from exposure to excessive solar radiation (e.g. Olivier 1975).

Conservation IUCN Category: Endangered C1. CITES: Appendix II (as *Hexaprotodon liberiensis*).

The range of this species has diminished dramatically in the past 100 years (Robinson 1970, 1971, 2003), but most acutely in the past 50 years. Forests within the historical range have been steadily logged, farmed, converted to plantations (rubber, coffee and oil palm) and settled, resulting in a fragmented distribution. Unchecked forest destruction and other damaging human disturbances, such as mining activities, pose serious threats to all remaining Pygmy Hippos and their forest habitats. Sierra Leone has important remnant populations in the Gola Forest region (Gola Rainforest N. P.) bordering Liberia (and also in the vicinity of Tiwai I. and in the Loma Mts), while Guinea contains isolated populations along the Liberian frontier (including in the Ziama Biosphere Reserve, and Diécké and Mont Béro Reserves) that are declining rapidly due to the impact of displaced Liberian war refugees. Côte d'Ivoire has lost most of its original forest cover, and, aside from remnant populations bordering Liberia, most hippos reside within Taï N. P. and N'Zo Faunal Reserve and surrounding areas and in Azagny N. P.

Liberia contains the most significant remaining forests suitable for Pygmy Hippos, with the greatest numbers in the central and south-eastern regions, where Sapo N. P. is the only protected area for this

species. However, this refuge has experienced significant encroachments from illegal mining and other human activities between 2002 and 2010, and the effects on Pygmy Hippo numbers remain undetermined. Extensive road-building, logging and settlement activities, accelerating in the 1990s, are destroying and isolating the remaining forest areas of SE Liberia, particularly in the Cestos and Senkwehn riversheds (Robinson & Suter 1999). Due to the exodus of rural Liberian refugees to urban settlements and neighbouring countries starting in 1989, wildlife populations in general rebounded during the Liberian civil war, but that trend is now reversing (P.T. Robinson & J. Suter pers. obs.).

The presence of the Pygmy Hippo may be a highly sensitive indicator of the degree of environmental disturbance; logging, hunting and settlement activities readily cause its disappearance, and seldom will it maintain a sustained presence within 5–10 km of such activities. However, Hentschel (1990) reports they will reoccupy secondary forests derived from logged areas. Primary methods of hunting this species are at night with headlamps and 12 gauge shotguns using solid metal projectiles, and with wire snares and pit traps. Captive animals are ordinarily pit-trapped or taken as young after killing the mother. Some wild-caught individuals have been said to become remarkably tame after very short periods in captivity (Schomburgk 1913).

The Basle Zoo in Switzerland records the most captive births and maintains the captive breeding studbook. Animals are readily maintained in zoos and breeding has been generally successful, with Basle, Washington and Pretoria zoos the most successful breeders (Hlavacek *et al.* 2005). The number held in captivity in 1988 was 340 animals, although the number of zoos exhibiting this species had decreased (Tobler 1988). As of Dec 2009, there were 332 (133 ♂♂, 196 ♀♀ and 3 individuals of unknown sex) known Pygmy Hippos in 134 public zoos and private collections. The captive population is descended from 61 wild-caught founder animals, unequally represented in collections. The last wild-caught individual was imported on 22 September 1982. The current captive population shows a skewed, female-biased, sex ratio and a relative lack of young animals (Mallon *et al.* 2011; and see Hlavacek *et al.* 2005).

In Nov 2010, a workshop was convened in Monrovia, Liberia, attended by representatives from all range states, government agencies, and local and international NGOs working on Pygmy Hippo conservation to develop a conservation strategy for the Pygmy Hippo with the goal to ensure the effective protection of, and connectivity between, known populations (Mallon *et al.* 2011).

Measurements

Chroeropsis liberiensis

TL: 1420–1570 mm, n = 4

WT: 179–273 kg, n = 7

Measurements from across the range (Lang 1975)

Height at the hindquarters for a ♂ and ♀, measured by Lang (1975), was 810 mm and 830 mm, respectively

The longest tusk on record measured 304 mm (Rowland Ward)

Philip T. Robinson

Suborder RUMINANTIA – Ruminants

Ruminantia Scopoli, 1777. *Introductio ad historiam naturalem*, Prague, pp. 493-496.

In the taxonomic upheaval that has accompanied the application of genetic analysis to traditional nomenclature, Ruminantia has emerged as the primary category for most, but not all of the two-toed, predominantly herbivorous mammals. The ruminants are subdivided into what might, in functional terms, be called 'proto-ruminants', the chevrotains or Tragulina, and the 'true ruminants' or Pecora, embracing the superfamilies Giraffoidea (giraffes), Cervoidea (deer) and Bovoidea (bovids). This division is well supported by molecular studies (e. g. Hassanin & Douzery 2003, Hassanin *et al.* 2012). The presence of the third forestomach compartment, the omasum, is a primary distinction between chevrotains, which lack this organ, and the Pecora or true ruminants. Extant tragulid species have become restricted in body mass and, although they were abundant and covered a wider body size range before the bovids evolved, they only survive today as relatively small forest dwellers in warm and humid climates.

For more than 100 years, scientists have known that only specific microbes can produce the enzymes necessary for breaking down the complex carbohydrates in plant material, and convert them into the coals of the fire of life, the sugars. The capacity to digest plant material is shared by many mammal groups, such as rodents, horses, rhinos and elephants, in which bacterial fermentation takes place in the hindgut ('hindgut fermenters'), and hippos, kangaroos or colobus monkeys, in which the microbes are housed in a forestomach ('foregut fermenters'). In foregut fermenters, the bacteria flowing out of the fermentation chamber are not lost in the faeces, but enter the glandular stomach (called the abomasum in ruminants), where they are killed by the hydrochloric acid produced in this compartment. The dead bacteria, consisting of highly digestible protein, thus contribute significantly to nutrition in foregut fermenters.

The products of bacterial fermentation of structural carbohydrates such as starch, cellulose, hemicellulose and pectin are always sugars, which are immediately used by the bacteria themselves; the metabolic products of their activity, namely three volatile fatty acids (VFAs), acetic, propionic and butyric acids, are absorbed by the mucosa of the fermentation chamber, be it the hindgut or the foregut. In ruminants, the rumen papillae increase the total mucosal surface, thus vastly enhancing the rumen's absorptive capacity. The rumen papillae are efficiently served by an intricate vascular system, which immediately transports these VFAs to the liver via the portal vein. The liver is vital not only for detoxification, but primarily, as in all herbivores, for re-synthesizing sugars, especially glucose, from these VFAs, a process known as gluconeogenesis.

The problem of toxins, or substances such as polyphenols that suppress digestibility (and are present in many plants, except grasses), may represent a particular advantage for a foregut fermentation system. In the foregut, the gut bacteria can metabolize toxic substances before they reach the sites of absorption in the small intestine. In ruminants, additional support comes from the salivary glands, which produce particular proteins that bind, for example, to the polyphenolic compounds in browse forage. Therefore, many non-grazing ruminants have a more viscous, protein-rich saliva produced in large salivary glands, whereas grazing species, which do not need this kind of defence,

Ruminant stomach. Rumen (R) derives from cardiac region of stomach. Reticulum (ret) is a muscular sac derived from a loop in the body of the stomach. Omasum (o) is a lesser curvature of gastric primordium. Abomasum (ab) represents pyloric atrium (after Young 1962).

have smaller salivary glands that, nevertheless, produce a copious, but more watery saliva.

The ruminant digestive system represents a unique evolutionary step forward by combining both the advantages of conventional microbial forestomach fermentation with a selective retention (and subsequent reprocessing) of large ingesta particles. This intensive use of ingested plant parts means that ruminants gain a comparable amount of daily energy from a distinctly lower amount of forage than non-ruminant herbivores. Ruminants 'chew the cud', but while we are so used to this well-known fact, we should not forget that this revolutionary adaptation necessitates a series of complicated morphophysiological adaptations. The sphincter cardiae (the barrier that prevents vomiting in horses and other animals) had to be removed. The smooth (i.e. involuntary) oesophageal musculature had to change into striated (voluntary) tissue. And in order for the rumination process to make sense, a sorting mechanism in the forestomach had to evolve to separate those particles that needed to be re-chewed from those that had already been digested and could pass on into the lower digestive tract.

Just how this sorting mechanism works is still a matter of debate. It is assumed that it is associated with the 'honeycomb' cells of the second forestomach, the reticulum, and the third forestomach, the omasum; both structures are much more pronounced in grazing ruminants. While the omasum provides a mucosal surface of about 2000 cm² in large browsers such as the Moose *Alces alces* or Greater Kudu *Tragelaphus strepsiceros*, this surface is enlarged up to more than 35,000 cm² in some grazing bovines! And it is in these species that evidence for a particularly effective and selective mode of particle retention has been generated. The fact that grazers excrete very fine particles in their faeces (in contrast to browsing species such as Moose or Greater Kudu) supports the notion that the mechanisms of particle retention and rumination are more effective in the more recently evolved grazing ruminants.

Thus, the forestomach anatomy of the tragulids (chevrotains or 'proto-ruminants') represents an evolutionarily older state, with no omasum at all. In true ruminants, the omasum was small to begin with, with few laminae, a sieve-like structure between the particle-sorting reticulum and the glandular abomasum. The evolutionary

success of the omasum structure can only be guessed at or inferred, partly by noting the displacement of tragulids from nearly all their previous ecological niches by true ruminants.

A time scale for ruminant evolution has been inferred by Hassanin *et al.* (2012), who used a Bayesian molecular clock approach as well as evidence from the fossil record. According to their calculations, the primary split between chevrotains and Pecora took place about 51.6 mya, which was well before grasses began to spread widely during the Miocene. So, rumination did not evolve directly in order to digest grass, as has sometimes been assumed. Thus, a high proportion of extant species (approximately 40% of all ruminants) have retained what could be called the early 'ruminant blueprint', both in the anatomy and the physiology of their digestive tract. These, often conservative, species are highly selective and avoid forage rich in cellulose, especially mature grass, which they are incapable of breaking down into a digestible form. They select fruit, litter and foliage with a low cellulose content, but rich in soluble nutrients, and with indigestible, lignified fibre. They chew with more vertical bites (puncture crushing), rather than grinding their teeth sideways. There is little stratification of ingesta in their rumen, in contrast to what occurs in grazers. This category of ruminants has been characterized as 'concentrate selectors' (Hofmann 1973); of the antilopine tribes recognized in this work, the Neotragini, Madoquini, Oreotragini, Raphicerini and Cephalophini are all 'concentrate selectors'.

Only some 25% of about 180 extant ruminant species are true 'grass and roughage feeders' (Hofmann 1973, 1989). These species have refined their ruminal physiology and anatomy to the point where they derive most of their energy from slow ruminal fermentation. This type of rumination mainly processes the cellulose that is provided by the grasses and composites that are now ubiquitous in the extensive grasslands of Africa and other continents. The more these larger ruminants adapted to cellulose digestion, the less important detoxification became, and this has resulted in diminished salivary glands and a relatively smaller liver.

There is also a large and significant category of opportunistic species that are intermediate between the two extremes mentioned above (Hofmann 1989). These 'intermediate strategists' comprise about 35% of all ruminants, and they are able to make use of both strategic avenues. They are especially well adapted to strong seasonality in African and other continental habitats because they can switch from grasses to browse material and vice versa (e.g. most cervids, Antilopini and Caprini). A recent literature review has synthesized dietary information for 78 species of African Bovidae (Gagnon & Chew 2000).

The evolution of ruminant diversity is far from being a linear process; rather, it is more like a bush (or even a baobab tree!) since completely different permutations and variations occur, some of them retaining 'older/conservative' features, while others incorporate innovative morphophysiological adaptations, especially when grass is their main resource.

There are evolutionary changes in the behaviour and morphology of those ruminants that ingest an increasing proportion of grass in their diet. Consuming more slow-fermenting cellulose fibre is accompanied by an increase in the size and capacity of both the rumen and the omasum (as well as changes in the molar teeth). In grazing species, rumination occupies a major portion of the daily activity budget. The exigencies of rumination and grinding cellulose fibre have caused changes in the shapes of mandibles, the fibre arrangement

Leptomeryx skeleton (primitive Oligocene chevrotain-like ruminant) (after Scott 1940).

of the masticatory muscles and the basic foraging apparatus. For example, pointed, delicate muzzles with manipulative lips transform into wide and rigid rostra, supported by the powerful gathering tongues that typify grazing bovines.

Some ruminants select forage with a high content of rapidly digestible (and maybe even soluble) nutrients and a rather indigestible (lignified) fibre component. These species, even when large in body size, have retained a relatively small rumen, permitting only a short retention of their ingesta. This results in short (intermittent) rumination periods and frequent foraging bouts. There are striking convergences between bovids and deer in the more conservative species; thus duikers resemble muntjacs in being small 'concentrate selectors', while the Greater Kudu and the Moose are both large browsers with poor cellulose digestion. In contrast to grazers, many non-grazing ruminants show solitary and cryptic behaviour.

There have been attempts to impose conceptual generalizations and categories on the overall trend from small, solitary, territorial browsers to large, social and hierarchical grazers. For example, Jarman (1974) concluded that both body mass and group size is negatively correlated to feeding selectivity, and group size is correlated with 'antipredator behaviour'. However, the diversity of specific adaptations ensures that there are many exceptions. For example, the largest extant ruminant does not fit into the scale of body mass interpretation: the Giraffe *Giraffa camelopardalis* is a browser with a short retention time and has a poor capacity for cellulose digestion. It is true that grazing ruminants are frequently on the large side – but rarely above 1000 kg (compared with a maximum of about 1500 kg for the Giraffe!). Likewise, the Oribi *Ourebia ourebia* is a grazing ruminant that only weighs 15–20 kg, another 'exception' that illustrates that ruminants have evolved unique forms for almost every exigency.

As the most widely distributed forage resource across all the continents, grass has become progressively more widely used by ruminants. Following long periods of adaptation across a wide span of the globe, the morphophysiological diversity of ruminants and the detailed structure of the rumination process in ruminants has changed and accommodated to many local permutations of climate, vegetation and ecology. Thus, the antecedents of grass-eating bovids had, almost

The Okapi *Okapia johnstoni* is one of several ruminants that have conspicuous chins. Such patterns effectively advertise the activity of chewing cud.

certainly, begun to differentiate on the basis of other biotic parameters well before the major expansions of grasslands (Kingdon 1982). The spectrum of surviving ruminant types offers many insights into evolution, especially among bovids, and has implications for classification and nomenclature that are still very largely unexplored. The briefest of surveys of living ruminants reveals that the digestion of grass was a specialization adopted independently by later members of several lineages (notably some Reduncini and Caprini and virtually all Hippotragini, Alcelaphini and Bovini) with concomitant development

of broad, deep molars. These ‘hypsodont’ species do not represent a single closely related entity, as was supposed until recently (Schlosser 1904, Eisenberg 1981).

In spite of substantial research on domestic stock, the livestock industry has failed to invest in research on the full adaptive range of ruminants and rumination, leaving the field to a handful of dedicated researchers in wildlife biology (e.g. Hofmann 1989, Jiang & Takatsuki 1999, Cerling *et al.* 2003, Sponheimer *et al.* 2003b, Hummel *et al.* 2005, Clauss *et al.* 2006). In the meantime, the politics of livestock promotion are destroying both ruminant diversity as well as the ecological diversity of African ecosystems. Because ruminant adaptive plasticity is an intensely interesting and useful process in its own right, and ruminant evolution appears to be still going on, a change of heart is long overdue. The livestock industry must modify its blinkered attitudes if conservation efforts are to succeed in retaining Africa’s ruminant diversity within their many native habitats; and change is overdue, not only in Africa.

Reino R. Hofmann & Jonathan Kingdon

Infraorder TRAGULINA – Chevrotains

Tragulina Flower, 1883. Proc. Zool. Soc. Lond. 1883: 184.

Lateral view of skull of late Eocene *Hypertragulus* (from Scott 1940).

Recent, molecular-led reformations in mammalian taxonomy support the majority of classifications that divide the order Ruminantia into two infraorders: the true ruminants, or Pecora (generally including those members possessing horns, antlers or ossicones), and the proto-ruminant chevrotain lineage, Tragulina (Hassanin & Douzery 2003, Hassanin *et al.* 2012; and see Hernández

Fernández & Vrba 2005). Since their divergence, some 51 mya (Hassanin *et al.* 2012), the pecoran lineage has diverged into more than 20 major lineages, which have continued to diversify right up to the present. Meanwhile, the chevrotains, after first registering in the fossil record in the late Eocene (in the form of *Archaeotragulus* from Thailand; Métais *et al.* 2001, and see Métais *et al.* 2007), remained a diverse and widely distributed group through the Miocene. They subsequently declined until only one representative remained in Africa, the Water Chevrotain *Hyemoschus aquaticus*. This decline was clearly strongly influenced by a less efficient digestive system than that of pecorans. Their likely ~50-million-year survival as a single lineage calls for the chevrotains’ continued existence to be registered at both infraordinal and superfamily level. In this work, as in most traditional treatments, tragulid peculiarities are described under the Family Tragulidae.

Jonathan Kingdon

Superfamily TRAGULOIDEA

CHEVROTAINS

Traguloidea Gill, 1872. Smithsonian Misc. Coll. 11 (230): 9.

The superfamily Traguloidea accommodates the ancient and once diverse chevrotains and mouse-deer. Chevrotains probably occupied a spectrum of early ruminant niches from at least the late Eocene

to the middle Miocene, but have been in decline ever since. The characteristics of chevrotains are summarized under their family profile, Tragulidae.

Family TRAGULIDAE

CHEVROTAINS

Tragulidae Milne-Edwards, 1864. Ann. Sci. Nat. Zool. Paris, ser. 5, 2: 157.

| | | |
|-------------------------------|------------------|-------|
| <i>Hyemoschus</i> (1 species) | Water Chevrotain | p. 88 |
|-------------------------------|------------------|-------|

The family Tragulidae occupies a threshold taxonomic position as ruminants. Most members of the suborder Ruminantia are also members of the infraorder Pecora comprising the extant families Moschidae (musk deer), Cervidae (deer), Antilocapridae (North American Pronghorn), Giraffidae (Giraffe and Okapi) and Bovidae (cattle, sheep, goats, antelopes). However, the more primitive tragulids are in their own infraorder, Tragulina. Nine tragulids occur in South-East Asia: six species in the genus *Tragulus* (Meijaard & Groves 2004, Grubb 2005) and three in the Indian genus *Moschiola* (Groves & Meijaard 2005). Only a single larger-sized species occurs in Africa, the Water Chevrotain *Hyemoschus aquaticus*, living in parts of the west and centre of the continent.

Tragulids are secretive little forest-dwelling animals with an unusual association with water. They have a cannon bone (lengthened and fused metapodials III and IV) in their back legs, but not always in the front legs. Their legs, especially in front, are not very long and the animals have a low crouched appearance when standing. Each foot has four digits, although in *Hyemoschus* the side digits do not touch the ground when standing. Tragulids lack the horns or antlers found in nearly all pecorans. The dental formula is $I^{0/3}, C^{1/1}, P^{3/3}, M^{3/3} = 34$. Males have curved upper canine tusks as in one or two pecorans such as musk deer, but of different cross-sectional shape; the lower canines look like incisors. Their molar teeth are less fully selenodont (with crescentic cusps) than in pecorans and the few cusps on the lower premolar teeth lie in an anteroposterior line and without additional or 'new' cusps on the lingual side (inside) of the original line. They have a compound stomach like that of pecorans, but without the omasum chamber, and rumination takes place in their digestion of food. Flower (1875) provided an exemplary account of the differences between the musk deer (a pecoran without horns or antlers) and tragulids.

The first fossil tragulid to be named was *Dorcatherium nauai* from early in the late Miocene (about 10 mya) of Germany (Kaup & Scholl 1834). Fortunately, the material included a complete skull. This skull differs from the living *Hyemoschus aquaticus*, which in 1834 had yet to be scientifically described and named, by being bigger (about one-fifth longer), having longer nasals, a preorbital fossa and a first lower premolar which had largely disappeared in ruminants even before 10 mya. Miocene Tragulidae are known from European countries other

than Germany, and also in East Africa, Arabia, India, South-East Asia and China. The largest African fossil species and some of the European species from about 18–10 mya differ from later tragulids by their less selenodont molars with more signs of their former bunodont (with low rounded cusps) condition. It seems likely that the family evolved in southern Eurasia or, just possibly, in Africa. They are known from early in the African Miocene and *Dorcatherium* is generally thought to have migrated into Europe at about 18 mya.

For about 170 years *Dorcatherium* was accepted as the earliest tragulid but, interestingly and anomalously, it is not known as far back in geological time as are pecorans. It occurs no earlier than about 22–20 mya, almost back to the start of the Miocene and a long time after the earliest pecorans, at around 34 mya. The pre-Miocene ruminants, going back to around 45 mya, constitute a varied array of animals with many primitive attributes, the earliest of them even possessing upper incisors and a long tail. They were evolving selenodont teeth with every sign of convergences and parallels between the lineages. Moreover some non-ruminants were also evolving various patterns of selenodonty. The earlier Oligocene *Lophiomyx* and its allies at around 30 mya lagged somewhat in the advance to selenodonty and were sometimes considered to be near tragulids. This could be true if it turns out that Tragulidae did not develop their apparently primitive characteristics as secondary reversals.

Métais *et al.* (2001; and see Métais *et al.* 2007) made a new and substantial contribution to this ongoing discussion by describing late Eocene (ca. 40 mya) fossil dentitions from Thailand, named by them *Archaeotragulus krabiensis*, as a member of the Tragulidae. However, ideas about the concepts and contents of early ruminant and near-ruminant families remain far from stable.

Tragulidae have been contracting their range since the middle of the Miocene epoch. By the late Miocene they were less common in Europe and by the end of that epoch they were extinct there. In East Africa, the latest cited occurrence is Miocene. In China, at the present day tragulids range only into a small southern area. This contraction is like that seen in the anthracotheres, of which the last survivor was the Indian *Merycopotamus* at around 3 mya. These declines must be linked with long-term climatic change leading to diminution of suitable wet-forest habitat and perhaps to the post-Miocene success of pecorans.

Alan Gentry

GENUS *Hyemoschus*

Water Chevrotain

Hyemoschus Gray, 1845. Ann. Mag. Nat. Hist. ser. 1, 16: 350.

Hyemoschus includes only the Water Chevrotain *H. aquaticus* of the West and central African rainforest. Water Chevrotains are small animals with short legs, large lateral hooves, a moderately long bushy tail and naked rhinarium. The limb bones are less reduced and co-ossified than in typical ruminants, with the ulna complete and separate from the radius, and metapodials II and V slender, but complete. Fusion

of the median metapodials is less advanced than in the related Indo-Malayan *Moschiola* and *Tragulus*, with metatarsals III and IV fused to form a cannon bone, but the suture is not complete and still visible, and metacarpals III and IV are unfused; all metapodials are very short.

Peter Grubb

Hyemoschus aquaticus WATER CHEVROTAIN

Fr. Chevrotain aquatique; Ger. Hirschferkel

Hyemoschus aquaticus (Ogilby, 1841). Proc. Zool. Soc. Lond. 1840: 35 [1841], Sierra Leone, Bulham Creek.

Taxonomy No subspecies have been recognized. The species is apparently monotypic across a large range, which is separated by the Dahomey Gap between the Upper Guinea and Congo Basin forest blocks. Synonyms: *batesi*, *cottoni*, *typicus*. Chromosome number: not known.

Description A squat, short-limbed, small-headed ungulate, with a compact body form, largest at the hindquarters, which are often held higher than the shoulders, and strongly tapered toward the head. Body covered with long-haired pelage overall umber brown to reddish-brown, grizzled with paler hairs, and marked with variably

Water Chevrotain *Hyemoschus aquaticus*.

Water Chevrotain *Hyemoschus aquaticus*.

distinct pale to white stripes and spots. The most distinctive white markings include longitudinally oriented white malar and neck patches offset by a darker line of pelage along the side of the neck, extending from below the chin and behind the gape area onto the neck. One to two variable longitudinal white stripes extend roughly in parallel along the sides of the body, gradually disappearing on the rump, and a series of pale dorsal spots, 1–3 cm in diameter are arranged as 6–7 irregular broken bands across the shoulder through the middle back. The small but somewhat elongated head narrows on the crown above large eye orbits and between relatively small ears that are dark on the outside with lighter hairs lining their inner surfaces. The hair on the crown is dark intermixed with variably lighter pelage around the eyes and on the muzzle. The eyes are dark brown and produce a whitish reflection when seen at night under torchlight. The chin and underparts of the neck are white, variably set off by dark brown line of pelage extending posteriorly from the upper chest. The lower chest and abdomen are grizzled brown. Tail dark brown above, white below, extending into a white fringe. The udder with four teats is covered with white hairs and located between the hindlegs. Hooves similar to other small to medium-sized ungulates, though slightly more rounded than those of the similarly sized forest duikers. Prominent hoofed metacarpals are present on all four limbs, though seldom visible in tracks.

Skull not unlike that of Indo-Malayan tragulid genera but more than one-and-a-half times longer, highest at the back and sloping down to the snout. The first incisors are broad. Other incisiform teeth have very narrow crowns; the cheekteeth are bunoselenodont, with relatively large sectorial premolars. Distinctive thin and strongly curved upper canine teeth (tusks) occur in both sexes, but are larger and externally visible in ♂♂.

Geographic Variation None recorded.

Similar Species The only tragulid representative in Africa, the Water Chevrotain is unmistakable. It shares its forest habitat with up to six species of duikers, which are similar in overall body size and share its primarily frugivorous diet. Water Chevrotain tracks might be confused with mid-sized duikers, especially as the print of the ‘dew hooves’ in their tracks is usually not evident. The Water Chevrotain is the only artiodactyl that can recline on its hind metatarsals and frequently does so as it settles to rest (Dubost 1968a, and see illustration in Kingdon 1979). The Neotropical caviomorph rodent, the Paca

Lateral, palatal and dorsal views of skull of Water Chevrotain *Hyemoschus aquaticus*.

Cuniculus paca, which is only slightly smaller than the Water Chevrotain, has a similar pelage and body form, a remarkable case of convergence in two unrelated species with comparable ecology and cursorial mode of existence (Dubost 1968a, Eisenberg & McKay 1974).

Distribution Endemic to West and central Africa; the distribution ranges across the forest belt from Sierra Leone and SE Guinea, through Liberia, S Côte d’Ivoire into SW Ghana. Grubb *et al.* (1998) discuss the validity of supposed records from west of Sierra Leone, concluding that, unless a record from the Kounounkan Forest in Guinea is substantiated (see Barnett *et al.* 1996), the furthest west the species has been reliably recorded is Sierra Leone. However,

Hyemoschus aquaticus

there are recent photographic records of the species from SE Guinea-Bissau in the Boé (P. Wit pers. comm.). The species is apparently absent from the Dahomey Gap, from E Ghana through Togo and Benin. Although formerly widely distributed in S Nigeria, East (1999) mapped it only east of the Niger R., from whence it ranges east through the central forest block, across S Cameroon, Gabon, Cabinda (Angola), Congo and DR Congo to extreme W Uganda, where it is now believed extirpated (East 1999). Crawford-Cabral & Veríssimo (2005) report a record from Angola from the Lunda Norte Province, near the Cassai R., which is the southernmost record of the species from the continent. The Water Chevrotain's occupancy of this range is highly discontinuous, being limited to the vicinity of streams and rivers. Forest loss and continuing forest degradation have further reduced suitable range in many areas, in particular in the remnant Upper Guinea forest block. Pickford *et al.* (2004) recently recovered remains of the Water Chevrotain from the early Pliocene in the Kenya Rift Valley.

Habitat Water Chevrotains are confined to closed-canopy, moist, tropical lowland forest, and within this habitat, they only occupy areas in the vicinity of streams and rivers. When disturbed, they frequently move to water, often using well-established trails and paths. If pursued, they may conceal themselves in the water by remaining still and almost entirely submerged beneath debris or under overhanging stream banks. The Water Chevrotain is not a swamp specialist, nor strictly limited to riverine forest, and often ranges, forages and even rests, in mature upland forest areas. But these areas are almost always within several hundred metres of streams and rivers large enough to provide cover (Dubost 1978). Water Chevrotains do not range out into gallery forests, or into forest savanna mosaic, even along river courses. This underlines the primary importance of large areas of mature evergreen forest for the survival of this species.

Abundance Overall distribution and abundance are limited by the proximity of suitably sized water-courses. In the Ituri Forest, densities have ranged from 1.5 to 5.0/km² (Hart 1985, 2000). Hoppe-Dominik *et al.* (2011) reported a density of 0.5/km² in Tâi N. P. based on transect counts. Much higher densities have been reported in Gabon, where up to 28/km² were recorded on an island in the Ivindo R. (Dubost 1978). East (1999) estimated the total population size at around 278,000 animals. However, given the differences in reported densities, and with current uncontrolled bushmeat hunting over much of its range, any attempt to compute overall current numbers is unrealistic.

Adaptations The Water Chevrotain, along with the Asian tragulids, is considered among the most primitive and conservative of ruminants. Tragulids are thought to have separated from the pecoran ruminants in the early Eocene (Hassanin & Douzery 2003). The Water Chevrotain retains many traits thought to characterize the earliest of the ruminants, including small body size, forest habitat and a selective 'concentrate' diet (Kingdon 1979). Many of the skeletal traits of the species are identical to those of the upper Miocene tragulid, *Dorcatherium*, which was discovered as a fossil before the living *Hyemoschus* was discovered in Africa (Turner & Anton 2004). Water Chevrotains exhibit some behavioural traits of the Suidae, including similar roles for olfactory signals and use of canines in intra-specific combat (Dubost 1975, Kingdon 1979). The

Water Chevrotain *Hyemoschus aquaticus* open-mouthed head myology.

overall adaptations of the Water Chevrotain suggest a species that is specialized for a stable but low energy trophic niche, coupled with a unique strategy for predator avoidance.

Water Chevrotains are nocturnal and spend the daylight hours resting, most often in concealed locations such as between tree buttresses, or in thick cover in tree falls, but surprisingly often in more open settings (Dubost 1978). This species relies on a complex pattern of light and dark colouration combined with immobility to provide camouflage and avoid detection. Resting animals remain immobile and may be approached to within just a couple of metres before they flush.

Water Chevrotains differ from sympatric duikers in their use of water as an avenue of escape. Black-fronted Duikers *Cephalophus nigrifrons* have specialized on swamp forests (an adaptation that is probably influenced by lower predator pressure), but Water Chevrotains, unlike Black-fronted Duikers, do not have elongated hooves and are the only small forest ungulates to actively conceal themselves by submersion in water. Water Chevrotains swim freely, although they are not sustained swimmers. Cinematography of the species under water has revealed that submerged animals move along the surface of the stream-bed using a walking gait reminiscent of submerged hippos (A. Root pers. comm.). The slit nostrils, which bear some resemblance to the valved nostrils of hippos, appear to be adapted to this aquatic escape mode.

Water Chevrotain dentition differs from that of similar sized frugivorous forest duikers in having thinner, finer-edged selenodont teeth that are weakly bedded in the skull, adapted to soft foods and ill-adapted to handle hard or coarse forage. The method of chewing resembles the shearing and cutting movements of some carnivores, and does not resemble the grinding and crushing mastication of other ungulates and suids (Dubost 1964). Water Chevrotains have a well-developed rumen and reticulum as in other foregut fermenting, pecoran ruminants but the omasum, at the posterior end of the fermentation chamber, is minimally developed. Thus the capacity to

Water Chevrotain *Hyemoschus aquaticus* skeleton.

Water Chevrotain *Hyemoschus aquaticus* myology.

retain food in fermentation chambers is limited (Hofmann 1973). The ratio of rumen volume to body weight is lower in the Water Chevrotain than it is in similar-sized sympatric frugivorous duikers, providing further evidence that the rumen is designed for rapid food turnover. This suggests that foregut fermentation in this species has evolved less for efficient breakdown of complex plant carbohydrates than to provide important detoxification functions for a diet that contains a wide range of digestion inhibitors and toxins. Chevrotains produce abundant saliva; this may capture and immobilize tannins, and other digestion deterrents and plant defensive toxins.

While the ability to handle plant toxins allows the Water Chevrotain to exploit a wide range of food sources, detoxification nevertheless incurs energetic and other costs. Water Chevrotains differ from many other ruminant ungulates in the strikingly pale colour of its flesh, in particular the musculature of the limbs. This is indicative of lower levels of myoglobin and lower metabolic capacity in the muscles. Unless they can reach water and find refuge quickly, Water Chevrotains that are flushed from hiding can be readily run down and captured, a characteristic exploited by the Mbuti hunters of the Ituri Forest, who sometimes capture animals by hand after flushing them from hiding and blocking their access to water.

Foraging and Food Fruits, seeds and fallen flowers, eaten from the forest floor, dominate the Water Chevrotain's diet. A wide variety of plant species have been reported in the diet from across its range (Gautier-Hion *et al.* 1980, Dubost 1984). A study of rumen contents taken from ungulate frugivores in the Ituri Forest (Water Chevrotain and six species of duikers) revealed that the Water Chevrotain had the most diverse diet on an annual basis ($n = 22$ stomachs) (Hart 1985). Important plant families in the diet include: Irvingiaceae, Sapotaceae, Euphorbiaceae, Apocynaceae, Sterculiaceae, Annonaceae, Ulmaceae, Sapindaceae and Meliaceae. Soft unripe fruits and unripe seeds were especially prominent in stomachs and included a number of species such as the Irvingiaceae, that were not recorded in diets when ripe. These food sources are all likely to contain protective chemical defences. Mast seed-fall of caesalpinaceous dominant canopy species, *Julbernardia seretii* and *Cynometra alexandri*, were also important seasonally. Animals captured by hunters during periods of mast seed-fall had layers of fat around their kidneys that were absent at other times of year. In Gabon, dicotyledonous families also dominate the

diet. In West Africa, the fruits of the abundant Marantaceae have been listed in the diet (Malbrant & Maclatchy 1949).

Dubost (1964) has suggested that meat may be a significant dietary item. In the Ituri Forest, Water Chevrotains as well as larger duikers, and Red River Hogs *Potamochoerus porcus* are known to feed on carcasses. Consumption of rotting carrion may even be advantageous for the ruminants, as the ammonia produced by the decaying protein is the most immediately available source of nitrogen for anaerobic microbial flora of the rumen. There are also reports that Water Chevrotain eat fish, insects and even aquatic plants (Dekeyser 1955). Rahm (1966) reports that Water Chevrotain are sometimes baited into traps with dead crabs or rats. His captive chevrotains readily ate live freshwater crabs offered to them. No evidence of these food sources was found in the rumens that were studied in the Ituri Forest (Hart 1985).

Social and Reproductive Behaviour Water Chevrotains are primarily solitary. Dubost (1978), describing a population on an island in the Ivindo R. in Gabon, reported stable and mostly exclusive female home-ranges of 13–14 ha, while ♂♂ had larger home-ranges of 20–30 ha that overlapped those of ♀♀, although they spent little time with them. In the Ituri Forest, in an area of small rivers and creeks, two radio-collared ♀♀ utilized home-ranges of 22 ha and 28 ha over the course of a year (J.A. Hart pers. obs.). They are irregularly active during the night, with periods of frequent movement alternating with periods when the animals are quiescent (Dubost 1978). In the Ituri Forest, radio-collared ♀♀ spent on average over 40% of each night resting.

Water Chevrotains have remarkably dense and thickened skins. This may protect the animals from injury in their encumbered environment; however, it also appears to protect against injuries in confrontations between conspecifics (Kingdon 1979). The canines are sharp and exposed. One ♂ caught in the Ituri Forest had a deep gash on its lower neck that might have been caused by a canine slash from a conspecific. Water Chevrotains have numerous epidermal glands, notably in the area under the chin. These are likely used in intra-specific marking, possibly in association with mating, but may also leave chemical signals at bedding sites. As yet there is no evidence for ritualized marking of home-ranges (faecal piles, rubbing posts, etc.). Dubost (1965) described a courting ♂ making brief cries as it approached and followed a receptive ♀. Local Mbuti

hunters attributed 'chuffing' barks heard at night in the Ituri Forest to this species.

Reproduction and Population Structure A single young is born after a gestation variably estimated at between four and nine months, and most likely in the region of 220 days (see Dubost & Feer 1992). In NE Gabon, births were recorded throughout the year, but with higher numbers in Dec, Jan, Apr, Aug and Sep (Dubost 1968b; and see Dubost & Feer 1992). In the Ituri Forest, births were also widely dispersed over the year. Of seven adult ♀♀, three (May, Jun and Sep) either carried full-term foetuses, or had recently given birth. Two young animals, both caught in Jan had been born in Dec. Four ♀♀ were not pregnant (Apr, Aug, Oct and Sep); another had been recently impregnated in Sep. The largest full-term foetus weighed 630 g (about 5% maternal weight). In the forests of Kivu (Utu area), Rahm (1966) reported that a ♀ pregnant at the time of her capture and kept in captivity with a ♂ gave birth in early Mar. Sixteen months later, in late Jul, the same ♀ died and was found to be bearing a full-term foetus. Water Chevrotains appear to grow quickly. In the Ituri Forest, ♀♀ with three molars and deciduous premolars had begun to breed, but no

animals with only two erupted molars were in breeding condition. Based on tooth eruption estimates by Dubost (1978), the estimated age of female maturation would fall between 20 and 24 months.

Predators, Parasites and Diseases Documented predators include Leopards *Panthera pardus* and possibly African Golden Cats *Profelis aurata*. In one study of Leopard diets in the Ituri Forest, Water Chevrotain remains were not as frequent in scats as those of nocturnal duikers (Hart, J. A. *et al.* 1996). It is possible that small ranges and limited movement by Water Chevrotains, even at night, in conjunction with their use of water as a refuge, may reduce vulnerability to predation. There is no information on parasites or diseases.

Conservation IUCN Category: Least Concern. CITES: Appendix III (Ghana).

Water Chevrotains appear to be rare, and may have disappeared from much of their historic range in West Africa. However, the species is still frequently encountered in many areas of central Africa, and is one of the preferred bushmeat species in the Kisangani region where its 'white' flesh is compared, somewhat exaggeratedly, to fish. In the central Ituri Forest, Water Chevrotains are regularly caught by the Mbuti net hunters (Hart 1979, 2000), consistently representing about 5% of total catch, even in areas that have been hunted for years. This low capture rate is probably due to the hunters' avoidance of riverine areas where chevrotains are most likely to occur. Water Chevrotains are particularly vulnerable to snares. One ♀, caught by Pygmy net hunters in the southern Ituri Forest, had a gangrenous snare wound on its front leg. Despite this, the animal had normal body weight and a full-term foetus. Water Chevrotains occur in a number of protected areas, including: Sapo N. P. and Grebo National Forest (Liberia), Tai N. P. (Côte d'Ivoire), Lobeke N. P. (Cameroon), Lope N. P. and Minkebe N. P. (Gabon), Maiko N. P., Kahuzi-Biega N. P. and Okapi Faunal Reserve (DR Congo) and Odzala N. P. and Nouabalé-Ndoki N. P. (Congo) (East 1999). Ultimately, Water Chevrotains will only be conserved by the protection of large areas of mature, undisturbed forest.

Measurements

Hyemoschus aquaticus

HB (sexes combined): 620–1020 mm*

T (sexes combined): 75–150 mm

E: 60 mm

Central Africa (Rahm 1966, Dubost 1975)

*Mean 725 mm (♂♂), 768 mm (♀♀)

Dubost (1975) cited a range of 7–15 kg with a mean 9.7 kg for ♂♂ and 12.0 kg for ♀♀. A sample of 13 adult body weights from the Ituri Forest (J. A. Hart pers. obs.) ranged from 9 to 13.5 kg with a mean of 10.3 kg for ♂♂ (n = 6), and 12.1 kg for ♀♀ (n = 7)

The longest tusk on record, from Cavallo R., Liberia, measured 57 mm (Rowland Ward)

Key References Dubost 1964, 1965, 1968a, b, 1975, 1984; Hart 1985, 2000; Rahm 1966.

Water Chevrotain *Hyemoschus aquaticus*.

Infraorder PECORA – Horned Ruminants

Pecora Linnaeus, 1758. Syst. Nat., 10th edn, 1: 65.

The Pecora embraces all the extant families of horned ruminants: Cervidae (deer), Giraffidae (Giraffe and Okapi), Bovidae (bovines and antelopes), Antilocapridae (pronghorns) and the hornless Moschidae (musk deer). The last are Asian, while Antilocapridae are exclusively North American. The Giraffidae are now entirely African, although they were also known in Eurasia until the late Pliocene. Inter-relationships between and within these families have been explored in some detail by several investigators using molecular and other techniques (e.g. Hassanin & Douzery 2003, Hernández Fernández & Vrba 2005, Hassanin *et al.* 2012; and see Prothero & Foss 2007).

The Pecora probably arose in the Eurasian land mass during the Eocene: the earliest pecorans were small and hornless (with narrow bladed upper canines in the ♂♂) and resembled modern tragulids (chevrotains) in size and general form, although both tragulids and pecorans are derived in their own different ways from the ancestral traguloid ruminant stock. According to Hassanin *et al.* (2012), the chevrotains branched away from the lineage leading to the Pecora in the Early Eocene, about 51 mya. There are substantial discrepancies between this molecular clock date and the first appearance of modern pecoran families in the fossil record at the start of the Miocene, around 23 mya (Cote 2010). However, there is a record during the Late Eocene of Thailand of a modern tragulid (Métais *et al.* 2001, 2007) and fossils are known from the Late Eocene and Oligocene of traguloids more derived than tragulids (e.g. leptomerycids), and primitive small, hornless pecorans (e.g. gelocids) (Prothero & Foss 2007). The latter would have resembled chevrotains in appearance, but shared a parallel-sided astragalus with other pecorans (Webb & Taylor 1980), indicative of greater cursorial specializations.

Modern pecorans are usually of larger body size, and are typified by the possession of horns, ossicones or antlers in ♂♂ (and even in the ♀♀ of some species and populations). The evolution of horns can sometimes be correlated with living at high densities, sometimes with territorialism, or with larger body masses. Remarkable as it may seem, it is likely that horns (or horn-like organs such as antlers and ossicones) evolved convergently several times, perhaps independently in each horned pecoran family. The living moschids are primitively without cranial appendages (Davis *et al.* 2011).

The mid-Eocene saw several climatic changes in the higher latitudes, but major changes in climate and vegetation only took place in the late Eocene (Hooker 2000, Janis 2007). The issue of timing is important because pecoran ruminants have some physiological advantages and anatomical features that can be correlated with at least two significant changes that are known to have taken place in the late Eocene. One was the development of more seasonal climates; another was an increase in leguminous plants (see Volume 1). Janis (2007) has suggested that the rise of the ruminants corresponded with an innovation in the way plants responded to changes in climate. Before the onset of marked seasons most plants grew thick and durable perennial leaves or leaflets. Up to this time herbivores were therefore adapted to bulk feeding on foliage that had cell walls rich in cellulose. These animals were fast throughput, hindgut digesters,

typified by the perissodactyls that were dominant during the Eocene, so what seems to be at issue in the late Eocene is the beginnings of a decline in bulk processing versus the initiation of selective feeding, possibly with a reduction in the quantity of available vegetation (Janis 2007). While late Eocene climatic changes seem to correlate with the diversification of ruminants in general, this cannot be tied specifically to the type of pecorans that we know today (the rise of the contemporary pecoran fauna is better correlated with changes in the early Miocene; Solounias & Dawson-Saunders 1988). It is only during the Pliocene that the species richness and composition of fossil bovid species starts to resemble the present (Bobe & Eck 2001).

Following the Eocene a great increase in deciduous leafing offered advantages to herbivores that could select out smaller quantities of higher quality foliage and extract more nutrients out of less material, even if the processing of food took longer to pass through the system. The ancestral Pecora may not have been as efficient at extracting and processing nutrients from deciduous foliage as some of the living, highly derived Bovidae or Cervidae, but the primary innovation in Pecora was development of a more advanced digestive capacity which is expressed today in the possession of a fourth forestomach compartment, the omasum. The omasum, situated between the fermentation chamber of the rumen-reticulum and the true stomach (abomasum), increases the digestive capacity of the foregut by enlarging its absorptive surface with extra papillae and laminae (the details of ruminant physiology are outlined in a later section). A primary innovation of the pecoran omasum is probably its conformation into a 'sieve' that helps sort and separate incompletely crushed particles from those digesta that are already sufficiently processed to proceed on their journey through the gut. This innovation helps make rumination much more efficient, but the exact course of its evolution must remain speculative.

While we cannot date the omasum back further than the common ancestor of extant pecorans (which certainly would not be as early as the late Eocene), it is, perhaps, by around the mid-Oligocene when animals such as *Amphitragulus* (an identifiable cervoid) appear as fossils and such a supposition becomes more secure. Rumination has the additional advantage of nitrogen cycling: dietary protein is fermented to form ammonia, which is converted to urea in the liver, and then fed back to the rumen bacteria. The protein actually digested by the animal is from the rumen microbes, which frees ruminants from needing to find all the essential amino acids in their diet. This cycle also ties in with waste urea, which allows for the conservation of urinary water, allowing ruminants to survive in drier habitats.

The craniodental morphology of early pecorans supports the notion of a relatively soft browsing diet and they would likely have had a rudimentary omasum and probably preferred highly nutritious vegetation, such as new shoots and fruit (a preference that is still evident in some bovids, cervids and giraffes). The selection of grasses as food only took place much later and this major shift into graminivory (mainly seen in the bovids, less so in the cervids) led to massive increases in the size of the omasum and the storage capacity of the foregut, together with appropriate modifications of salivary

glands, livers, teeth and chewing apparatus. The development of selenodont cheekteeth seems likely to be coincident with the development of foregut fermentation, the former first appearing in the late Eocene. It has been pointed out that browsing ruminants can be as much as 400 kg heavier than the largest grazing ruminant (giraffe ♀♀ may average about 1200 kg): this is because, with enlargement, ‘packing constraints’ and the production of methane within the abdomen eventually constrain roughage grazers (Clauss *et al.* 2003). Thus, the African Buffalo *Syncerus caffer*, with an enormous rumen, is probably not very far short of that threshold.

Deer are only peripheral to Africa, being particularly successful in temperate latitudes of Eurasia, but with extensions into lower latitudes

in the Americas and Eurasia. Bovids have the broadest geographic range, although unlike cervids they never extended their range into South America. The early Miocene African fossil record is sparse, and at the moment we cannot be certain when bovids entered the continent. Some primitive pecorans of unknown taxonomic affinity are known from around 20 mya (Cote 2010), but definitive bovids are not present until around 17 mya, and it was not until around 15 mya that they (along with giraffids) became a significant part of the fauna (Gentry 2010). The radiation of antelopes, the most successful of pecorans in Africa, is discussed elsewhere in this volume.

Christine Janis & Jonathan Kingdon

Superfamily GIRAFFOIDEA

GIRAFFE, OKAPI

Giraffoidea Gray, 1821. London Med. Repos. 15: 307.

The giraffes are one of four extant groups of ruminating herbivores in Africa: chevrotains (Tragulidae), deer (Cervidae) and bovids (Bovidae) being the others; the Pronghorn *Antilocapra americana* (Antilocapridae) and musk deer (Moschidae) are exclusively American and Asiatic. Today differences are obvious, but from comparing their anatomy (especially teeth), and from their fossil history, it is clear that giraffoids share a common origin with deer (more distantly with the bovids and more distant still, the chevrotains). Molecular clocks estimate the divergence between protogiraffes and protocervid/bovids as occurring about 23.4 mya, while the tragulid/pecoran divergence was closer to 51 mya (Hassanin *et al.* 2012). It is possible that a combined examination of differences in geography, climatic adaptation, body-size, limb proportions, fossils, phylogeny and genes may eventually help explain the origins of differentiation between cervoids and the earliest giraffoids.

The region of origin for cervoids is undoubtedly Eurasia, probably temperate Eurasia. Because the first known fossil giraffe had been found in the 1840s from the Siwalik Hills (*G. sivalensis*), there has long been a presumption that giraffes might have originated in the sub-tropical Indian sub-continent. Given that fossil giraffoids are diverse and well represented in India, this remains a possibility, but the genus *Giraffa* is far too late (evolving only 7–8 mya) to indicate the origins of the superfamily. None the less, the genus *Giraffa* may well have originated in India, and Harris (1991b) considered *G. punjabiensis* the oldest member of the genus (7.3–7.1 mya) and the one most like *Bohlinia*, a widely distributed proto-*Giraffa*.

Giraffoidea had branched into two different families long before the 8-million-year-old *G. sivalensis* and *G. punjabiensis*. The Climacoceratidae are long extinct while modern Giraffes and Okapis exemplify the Giraffidae. Some resemblance between the earliest cervoids and giraffoids are exemplified by the deer-sized, deer-shaped *Climacoceras africanus* (a social herbivore that is common in East African deposits of about 17–15 mya), which had very long, spike-like male ‘antlers’ with short ‘tines’ sprouting along their length; however, it should be noted that Harris *et al.* (2010) recognize Climacoceratidae and Giraffidae as separate families.

In spite of superficial similarities, the physiological origins of giraffoid bony ossicones and non-bony deer antlers differ, although both structures probably derive from damage-minimizing or healing processes on the crania of ancestral stocks. Selection for what began as wound-generated lumps and bumps (that incidentally served *defensive* purposes) eventually became selection for species-specific cones, of dermal origin, with growth patterns that, in the giraffes, transformed cranial structures into genetically programmed, explicitly *offensive* weapons. If correct, this evolutionary progression illustrates the primacy of defensive behaviour and structures, while weapons tend to be secondary structures that become integrated into earlier defensive structures. Most giraffoid genera have ossicones in both sexes. The sivathere *Helladotherium* had ♀♀ without ossicones but that seemed to be the exception rather than the rule.

The earliest known fossil form of giraffine is *Canthumeryx sirtensis*. This fossil was discovered in deposits near Gebel Zelten some 200 miles south of Tunis, which is now desert but at the time of *Canthumeryx* was a flourishing alluvial/flood-plain/savanna/river basin habitat. *Canthumeryx* was a medium-sized antelope, about the same size as a Fallow Deer *Dama dama*, and with the characteristic bilobed giraffoid lower canines (Hamilton 1973, 1978).

Body-size differences clearly separate modern giraffes and deer; even greater contrasts existed between the well-named *Sivatherium giganteum* and any fossil cervid. So, at some quite early stage of the divergence between the giraffe and deer lineages, size may well have become a decisive factor. Large size would have included the advantage of higher feeding zones: thereafter, the elongation of both limbs and necks would have been selectively favoured, because it offered still greater access to high-quality food resources that were out of reach for other herbivores. There are interesting comparisons here to be made with the Gerenuk *Litocranius walleri*, which stands on its hindlegs to augment an already exceptional reach.

A summary of the characteristics of living Giraffoidea can be found in the family and generic profiles and warrants no repetition here.

Jonathan Kingdon & John M. Harris

Family GIRAFFIDAE

GIRAFFE, OKAPI

Giraffidae Gray, 1821. London Med. Repos. 15: 307.

| | | |
|----------------------------|---------|--------|
| <i>Giraffa</i> (1 species) | Giraffe | p. 96 |
| <i>Okapia</i> (1 species) | Okapi | p. 110 |

European peoples of the past were familiar with deer (family Cervidae) in the wild places of their own continent. They would also have known of Bovidae as sheep, goats and cattle in their farmed countryside and as ibexes and chamois in the mountains. Some had heard of gazelles in the great desert belt south of the temperate lands, and when Africa was explored it was found to be full of antelopes (Bovidae again). So Cervidae were found in Eurasia, while Bovidae concentrated in Africa. In addition, a single, spectacular large African pecoran ruminant, the Giraffe *Giraffa camelopardalis*, belonged to a different family, the Giraffidae, and in 1901 a second giraffid, the Okapi *Okapia johnstoni*, was discovered in Africa.

The Giraffe and Okapi are large ruminants with long legs and long necks. Both species have somewhat toughened skin over their bony horns, present in both sexes in the Giraffe, but only in ♂♂ in the Okapi. Both have a dental formula of $I^{0/3}, C^{0/1}, P^{3/3}, M^{3/3} = 32$ (Singer & Boné 1960), with small and low-crowned cheekteeth, bilobed lower canines and prehensile tongues. They browse off shrubs and trees well above ground level, yet the Giraffe is an open-country or bushland inhabitant, sometimes in quite dry areas, whereas the Okapi is a true forest inhabitant. It is interesting and instructive that such similar cheekteeth can be found in species of such contrasted habitats.

The earlier relatives of Giraffes go back to early in the Miocene epoch, before 20 mya, in Africa (Morales *et al.* 1999) and perhaps elsewhere. Conclusions about their ultimate continent of origin are much influenced by molecular phylogenies that still do not agree on which pecoran family is most closely related to Giraffidae. Price *et al.* (2005) and others (see Meredith *et al.* 2011, Hassanin *et al.* 2012) have even suggested the North American Antilocapridae, which, it has to be remembered, descend from immigrants from the Old World.

According to Harris *et al.* (2010), the family Giraffidae contains the subfamilies Canthumerycinae, Bohlininae, Giraffokerycinae, Sivatheriinae, Palaeotraginae and the living Okapiinae and Giraffinae. The first unequivocal giraffids, animals like *Canthumeryx* and *Injanatherium*, have been found as fossils from Africa to Pakistan, also in south-eastern Europe and their descendants to other parts of Asia. These early giraffids were large ruminants for their period (17–10 mya) and had widely divergent horns with spreading bases broadened in an anteroposterior direction and flattened mediolaterally. Sometimes they had a small anterior pair of horns in front of the orbits in addition to the main pair, but the nature of the skin covering of the horns is unknown. Their cannon bones or metapodials were longer than in the various deer and antelopes living alongside them.

Coincidental with the arrival of three-toed hipparionine horses from North America between 11 and 10 mya, Old World ruminant faunas changed. Two subfamilies of more advanced giraffids appeared: Giraffinae and Sivatheriinae. Sivatheres started grazing with the spread of C₄ grasses (J. Harris pers. comm.) and became very large and

Sivatherium giganteum skull in anterior view (left); skull of Miocene giraffid *Giraffokeryx punjabiensis* in dorsal view (top right) and lateral view (bottom right).

bulky, heavy-headed animals with branched or bulbously-tined horns, retaining an anterior pair of horns, and re-evolving somewhat shorter cannon bones. They persisted into the Pleistocene in India and Africa, in the latter until 500,000 years ago or possibly later. They became extinct presumably for the same reason that caused the demise of the large grazing bovids (*Pelorovis*, *Megalotragus*) and giant grazing pigs.

The common Eurasian late Miocene giraffines are a separate development from whatever stock gave rise to modern *Giraffa*. Some of them approach hypsodonty in their teeth, and microwear studies have shown that they must have grazed. In this they are very unlike *Giraffa*, as also in that their legs were not invariably lengthened to the same great extent. After flourishing for several million years they declined and later became extinct in the Pliocene.

The precise phylogenetic position of *Okapia* is unclear, the key question being whether it split recently from *Giraffa* or whether it has a long-separate ancestry. Its most obvious difference from Eurasian Miocene giraffes is the closeness of the two horn insertions. This might be considered adaptive for forest dwelling, except that the same character is found in *Giraffa*. There are wide disparities between fossil, molecular and other estimates for the divergence between *Giraffa* and *Okapia*. Molecular clocks suggest a divergence at 15 mya (Hassanin *et al.* 2012), while other reviewers have posited 8 mya (Mitchell & Skinner 2003).

It can be surmised that giraffid ruminants survived by becoming larger than other ruminants, but their Eurasian radiation was curtailed after the end of the Miocene. In Africa both *Okapia* and *Giraffa* specialized in a capability for high-level browsing, one in forests and one in savannas, but sivatheres failed to survive to the present day. *Giraffa* was also found for a long time in India but the date of its extinction there is not known. It can almost be thought of as an unfortunate historical or evolutionary accident that Giraffidae have become confined to the continent of their probable origin.

Alan Gentry

Subfamily GIRAFFINAE – Giraffe

Giraffinae Gray, 1821. London Med. Repos. 15: 307.

Subfamily Giraffinae is a monotypic subfamily, represented by a single surviving species, the Giraffe *Giraffa camelopardalis*.

GENUS *Giraffa*

Giraffe

Giraffa Brisson, 1762. Regn Anim., 2nd edn, pp. 12, 37.

The Giraffe, *Giraffa camelopardalis*, is the only extant representative of the genus *Giraffa*. Together with the only other living giraffid, the Okapi *Okapia johnstoni*, they represent the extant members of a previously more diverse group.

Not long after the description of the species, Levaillant in 1790 described the southern giraffe as a separate species (Dagg & Foster 1982). This separation between northern and southern species

continued through the 1800s (Owen 1841, Lesson 1842; although see Ogilby 1836). Thomas (1901) separated the reticulated giraffe *Giraffa reticulata* as a separate species from all other forms of Giraffe, and this was maintained by Lydekker (1904). Subsequent authors followed either classification scheme: Dollman (1929) and Allen (1939) separated the reticulated giraffe as a separate species, while Stott (1959) maintained the northern versus southern species split. However, for much of the latter half of the twentieth century, only a single living species of Giraffe has been recognized. More recently, Brown *et al.* (2007) identified six genetically distinct lineages, with little evidence of interbreeding between them, and proposed that some may represent distinct species.

The most obvious features of *Giraffa* are the long limbs and neck. Where paired cranial appendages occur in ruminants they are on the frontal bones in a lateral supraorbital position. In *Giraffa* the paired ossicones are dermal in origin and attach to the skull more posteriorly over the frontoparietal suture. These ossicones are straight with rounded ends and vary individually in form (Singer & Boné 1960). In extant Giraffes the parietal ossicones show strong sexual dimorphism (Dagg 1965, Seymour 2001). The lower incisors and canines are robust and arranged in a semi-circular arcade. The lower canine is typically bifid and occasionally trifid. The cheekteeth are variable in size between species, with premolars relatively complex. Basicranial and basifacial planes typically are not parallel and skull flexion varies individually in the species (Seymour 2001).

The genus has an Asian origin, with the earliest known African specimens of *Giraffa* originating from fossil beds dating to the late Miocene and early Pliocene of Kenya and the early Pliocene of South Africa (Churcher 1978). Churcher (1978) described four extinct members of the genus *Giraffa* in Africa besides the extant species: *G. jumae*, *G. stillei*, *G. gracilis* and *G. pygmaea*. More recently, Gentry (1997) – following Harris (1987, 1991b) – accepted three extinct species, with *G. gracilis* included in *G. stillei*.

Giraffa jumae is known from localities in East Africa and South Africa (though Harris [1976] gives *Giraffa* cf. *G. jumae* at Langebaanweg) dated from the early Pliocene to middle Pleistocene. The South African specimens are isolated teeth and ossicones, while the East African material is more substantial. The species is founded on a nearly complete skull and mandible with a significant proportion of the postcranial skeleton. *Giraffa jumae* specimens are typically larger than contemporary *G. camelopardalis*. While the dimensions of the skull are greater, the teeth are similar in absolute size in comparison between the two species. The ossicones of *G. jumae* originate directly behind the orbital rim, further forward than in *G. camelopardalis*, and extend back parallel to the plane of the skull. The parietal horns end

Giraffe *Giraffa camelopardalis* skeleton.

Giraffe *Giraffa camelopardalis* skull outlines (bottom) compared with Plio-Pleistocene *Giraffa jumae* (top).

in knobs. No median horn has been identified in specimens assigned to *G. jumae*. No secondary bone deposition is apparent and the occipital ridge is not enlarged. In accord with the larger cranium, the mandible is more substantial than in *G. camelopardalis*, curving upwards through the diastema and downwards in the incisor region.

Giraffa stillei, from the early Pliocene to early middle Pleistocene of East Africa, was first described as an Okapi based on dental characters and forelimb anatomy. Harris (1976) rediagnosed these specimens to *Giraffa*, according to the premolar morphology. Churcher (1978) suggested that the dental characters used to diagnose this taxon were highly individually variable and showed greater affinity to another giraffid genus, *Palaeotragus*. Churcher (1978) suggested that, without additional material, the affinities of the specimens currently assigned to *G. stillei* remained controversial. However, Harris (1987, 1991b) and Gentry (1997) accepted *G. stillei* and subsumed *G. gracilis* into it.

Specimens of *Giraffa gracilis* have been found in East Africa and possibly in South Africa from beds dating from the late Pliocene to late Pleistocene. The limb bones and neck are of similar absolute length to *G. camelopardalis* but are more lightly constructed and show finer proportions in all parts of the skeleton. Dental characters also differ. The bases of the ossicones are oval in cross-section, smaller than in *G. camelopardalis* or *G. jumae* and oriented at the same angle as in the modern giraffe. Secondary bone deposition occurs over the ossicones. The area between the orbits is convex (Harris 1976) and may or may not have a median horn present. Churcher (1978) suggested that, despite generalizations about the relative size of *G. jumae*, *G. camelopardalis* and *G. gracilis*, the skeletal elements overlapped in size between these purported species making size alone an unreliable character for species identification.

A *Giraffa* species with ossicones smaller and more delicate than those of *G. gracilis* and flattened on the posterolateral surfaces occurs in the early Pleistocene of East Africa. *Giraffa pygmaea* shows (presumed) sexual dimorphism with secondary bone deposition occurring in the (presumed) ♂♂, increasing the proportions of the ossicones relative to the (presumed) ♀♀. Dental characters are typically giraffine, but differ from other species by their small size. Churcher (1978) considered this species to be inadequately defined for certain recognition as a separate species.

Giraffe *Giraffa camelopardalis* myology.

Many of the African *Giraffa* species are based on relatively little material and the status of some species may be equivocal. Many fossil specimens were originally attributed to *G. camelopardalis* and have subsequently been reassigned to the extinct species, bringing forward the earliest recorded fossils of the modern giraffe. Contemporary giraffes vary individually, sexually and geographically in size while skull morphology is also highly variable within the extant taxon. As many of the described differences (particularly in size) may represent extremes of continuous variation further fossil material is necessary to substantiate the status of the species within *Giraffa*. Mitchell & Skinner (2003) reviewed the origin and evolution of Giraffes, while Mitchell (2009) provides a review of the scientific study and classification of Giraffes.

Russell Seymour

Giraffa camelopardalis GIRAFFE

Fr. Girafe; Ger. Giraffe

Giraffa camelopardalis (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 66. 'Habitat in Æthiopia et Sennar'; identified as Egypt, in captivity at Cairo (Thomas 1911: 150); restricted to Sudan, Sennar, by Harper (1940: 322).

Masai Giraffe *Giraffa camelopardalis tippelskirchi*.

Taxonomy The Giraffe is here considered a polytypic species comprising eight subspecies (and see genus profile). Numerous subspecies have been recognized (e. g. Lydekker 1904), although most recent treatments have acknowledged nine (Ansell 1972, Dagg 1971, Dagg & Foster 1982), eight (Kingdon 1997), or six (East 1999, Grubb 2005). Based on pelage patterns, skull morphology and mitochondrial DNA analysis, Seymour (2001) described six or seven subspecies, and the existence of a distinct northern and southern clade. Considerable uncertainty surrounds the geographic and taxonomic limits of all described subspecies, as well as intergrades or hybrids between supposed subspecies (especially between *reticulata* and *tippelskirchi* in E Kenya; Kingdon 1979, Stott & Selsor 1981). Pelage patterning within subspecies highlights this uncertainty. As a definable characteristic, it is unreliable due to the high degree of individuality and variability within a population, ranging from albino and pure white through pale brown and unspotted to black (Mitchell & Skinner 2003, Fennessy 2004). Many of these variations exist within regionally definable patterns, although these boundaries are often far from clear.

Brown *et al.* (2007) analysed mitochondrial DNA sequences and nuclear microsatellite loci from six of the nine subspecies defined by

Dagg & Foster (1982). They identified six genetically distinct lineages (*peralta*, *rothschildi*, *reticulata*, *tippelskirchi*, *giraffa* and *angolensis*), with little evidence of interbreeding between them, and 11 genetically distinct populations. According to these authors, neighbouring subspecies as well as those that are geographically separated are essentially reproductively isolated, suggesting that some may represent distinct species rather than a single polytypic form. Synonyms: *aethiopica*, *angolensis*, *antiquorum*, *australis*, *biturigum*, *capensis*, *congoensis*, *cottoni*, *giraffa*, *hagenbecki*, *infumata*, *maculata*, *nigrescens*, *peralta*, *renatae*, *reticulata*, *rothschildi*, *schillingsi*, *senaariensis*, *thornicrofti*, *tippelskirchi*, *wardi*. Chromosome number: $2n = 30$ ($FN = 54$). The 28 paired autosomes are mainly metacentric and submetacentric with one pair of acrocentric chromosomes, which are small; the large X chromosomes are submetacentric and the small Y chromosomes metacentric (Wallace & Fairall 1965, Gallagher *et al.* 1994).

Description The tallest of all animals, the Giraffe is characterized by its greatly elongated neck and long limbs. Males, which are taller than ♀♀, range between about 4 and 5 m in height, with records of individuals up to 5.9 m (Shortridge 1934). Shoulders appear higher than the croup, a characteristic enhanced by the long spines of the thoracic vertebrae (see Adaptations). Neck fringed with a short, thick mane. Ears narrow and pointed, eyes large. Pelage short, with a highly characteristic pattern of large, irregularly shaped, dark patches separated by a network of light-coloured bands. This patterning, which extends from about the chin to the limbs, varies predominantly from chestnut-brown to nearly black. Kingdon (1979) considered that all Giraffe network patterns were products of interaction between two different, and genetically controlled, spot formation systems whereby light spots never occur in isolation, whereas dark spots are always isolated unless clustered within a single 'island' of ground colour. Leucistic Giraffes have been recorded (e.g. Tarangire N. P. and Rukwa in Tanzania, and Masai Mara in Kenya; C. Foley pers. comm.). The individuals (both ♂♂) in Tarangire N. P. were predominantly white, though they had regular brown colouration on the lower legs and some black markings on the upper body (C. Foley pers. comm.). Colour and pattern also varies individually, being unique to each Giraffe (although local lineage characteristics can sometimes be recognized). Overall patterns, especially the dark patches, generally tend to darken with age. Towards the hooves the limbs are generally lighter in tone, but there are regional distinctions in the extent of patterned or unpatterned 'socks'. The skin pigmentation is uniformly dark grey. Tail with black terminal tuft. There are no compound odoriferous glands. Two pairs inguinal nipples.

The skull is long, sometimes more than 700 mm, and is characterized by extensive pneumatic sinuses. A characteristic feature of adults is the two or three short, blunt 'horns', more correctly termed ossicones, which rise from the top of the skull. These comprise a parietal pair, and a single median ossicone. Ossicones are covered with skin and hair, and are present in both sexes, but are thinner and with more prominent

Lateral, palatal and dorsal views of skull of adult male Reticulated Giraffe *Giraffa camelopardalis reticulata*.

tufts of hair in ♀♀ and young. The median ossicone, which originates primarily on the frontal bone and the posterior portion of the nasal bone, is less prominent in ♀♀ (sometimes just represented by a bulge) and represents a secondary sexual male character (Spinage 1993). The Giraffe is the only ruminant with paired parietal horns present in the foetus. These ossicones begin as fibro-cartilaginous discs and are not attached to the skull (Owen 1849); they lie against the skull and present no obstruction at birth (Naaktgeboren 1969). They progressively ossify and enlarge, fusing to the skull later in life (about 4–4.5 years in ♂♂ and 7 years in ♀♀) by way of secondary bone deposits (Spinage 1968). The median horn develops in the same manner as the parietal horns (Spinage 1993). Secondary bone deposits may accumulate on male skulls, producing further bony growths. Male skulls often develop rugosities that can resemble supernumerary horns, especially on the nuchal crest (see Adaptations).

The permanent teeth erupt at about three years of age, except for the canines that erupt at around six years (Hall-Martin 1976). No dental abnormalities have been recorded (Colyer 1936, Miles & Grigson 1990).

Geographic Variation The treatment of subspecies presented here is provisional, and largely follows East (1999) except for separation of *giraffa* and *angolensis* (Seymour 2001, Fennessy 2004) and *peralta* and *antiquorum* (following Hassanin *et al.* 2007).

G. c. peralta (Niger or West African Giraffe): Niger. Wider pale bands; the edges of the spots, though somewhat crenulate, are strongly delineated from the paler ground colour. Males have the strongly formed median horn (as in all northern giraffes), but it tends to be more cylindrical (as opposed to conical). Recognized as a distinct subspecies by Hassanin *et al.* (2007).

G. c. antiquorum (including *congoensis*) (Kordofan Giraffe): N Cameroon, S Chad, Central African Republic, W Sudan and presumably NE DR Congo. The blotches, which often appear coarsely divided or constricted, extend below the hocks.

G. c. camelopardalis (including *rothschildi*) and *cottoni* (Nubian, Rothschild's, or Baringo Giraffe): Ethiopia, Kenya, Sudan, Uganda. The blotches are more widely separated than in *reticulata*. The inner sides of the legs are unspotted, with the legs pure white below the hocks. Generally very large body size, especially ♂♂. Although provisionally included in *G. c. camelopardalis* here, the form *rothschildi* may represent, and is often treated as, a distinct subspecies (e.g. see Brown *et al.* 2007).

G. c. reticulata (Reticulated Giraffe): Ethiopia, Somalia, Kenya. The large, almost polyhedral patches are placed closely together with only a fine network of light colour dividing them. Patterning may be very dark in old animals. Generally smaller body size. Integrates with *G. c. reticulata* and *G. c. tippelskirchi* have been recorded (Stott 1959, Stott & Selsor 1981).

G. c. tippelskirchi (Masai Giraffe): Kenya and Tanzania. The blotches are typically deeply dissected, forming all shapes of sharply differentiated leaf or stellate designs. The patterning always continues down to the hooves.

G. c. thornicrofti (Thornicroft's Giraffe): Luangwa Valley, Zambia. Slightly stellate spots, which become oblong on the neck. The neck is usually lighter in colour than the body and the legs are fully patterned.

G. c. angolensis (including *infumata*) (Angolan Giraffe): Namibia, SW Zambia, N Botswana, extreme W Zimbabwe; formerly in Angola, but now probably extinct. Considered as a distinct subspecies based on recent molecular evidence (Seymour 2001, Fennessy 2004, Hassanin *et al.* 2007).

G. c. giraffa (including *capensis* and *wardi*) (Southern or Cape Giraffe): South Africa, S and SE Zimbabwe and SW Mozambique. The blotches, which extend down to the hooves, are more or less round. The colouring may be very dark. Generally large body size.

Similar Species Given its distinctive features, the Giraffe is unlikely to be confused with any other animal.

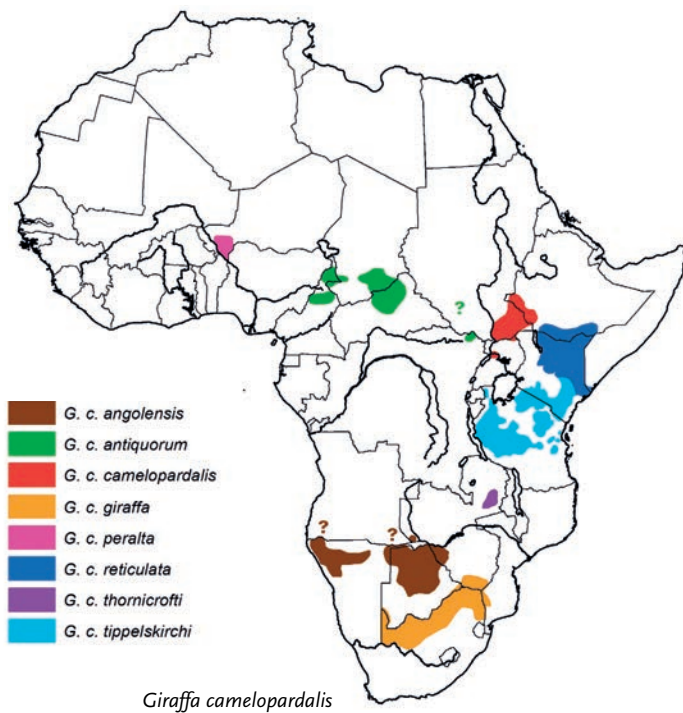

Distribution Endemic to Africa.

Historical Distribution Widespread in N and W Africa, including the Sahara, until the Neolithic. Rock drawings, petroglyphs and skeletons confirm their presence on the banks of the Nile and the plateau of Messak until 4000 BC and later in the Western Sahara and Mauritania (Le Quellec 1999).

Giraffes were historically distributed widely throughout the Sahelian regions of West Africa from C and E Senegal, N Guinea and SE Mauritania through C Mali to C/S Chad, N Central African Republic, Sudan (west of the Nile) and NE DR Congo.

Nubian/Rothschild's Giraffes occurred in SW Eritrea and W and SW Ethiopia, south through Sudan, east of the Nile R., Uganda and W Kenya. Reticulated Giraffes ranged from S Ethiopia south through Kenya, east of the Rift, adjacent S Somalia to north of the Tana R. Masai Giraffes occupied S and E Kenya and much of Tanzania north of the Rufiji R. Thornicroft's Giraffes occurred only in the Luangwa Valley in Zambia (Ansell 1978). There is one exceptional occurrence of a Giraffe being recorded in Malawi (a single individual killed in Sep 1976), presumably a vagrant animal from the Luangwa Valley (see Ansell & Dowsett 1988).

The historical ranges of the two southern subspecies (*giraffa* and *angolensis*) covered Namibia (including the semi-desert areas of Kaokoland in the north-west) and adjacent parts of S Angola (in two

well-separated populations in the SW and SE), N and C Botswana, SW Zambia, W and S Zimbabwe, S Mozambique, and N and NE South Africa (East 1999). Although some have proposed that Giraffe never occurred south of the Komati R. in Swaziland or KwaZulu-Natal (Goodman & Tomkinson 1987), Giraffe were probably present 1000 BP in KwaZulu-Natal, but had died out or been extirpated by ca. 220 BP (Cramer & Mazel 2007). Indigenous San drawings suggest that Giraffe once occurred throughout parts of S South Africa: near Queenstown, in the Tarka area, near Graaff Reinet and on the Tsomo R. around 1650. However, over a period of 300 years, the limit of their range was reduced by nearly 900 km (Dagg & Foster 1982).

Current Distribution Today no Giraffes survive in North Africa, though some may have remained in Morocco as late as 600 AD (Schomber & Kock 1961). The beginning of the twentieth century marks the sharp decline of Giraffes in the West African region. The only surviving population in West Africa is in SW Niger, an area of approximately 15,000 km² delineated as the 'giraffe zone' in a broader Biosphere Reserve. This population co-habits with subsistence agricultural communities and seasonally migrates throughout its range in search of available forage. During the wet season (Jun–Sep), the animals are located on the Koure and Fandou Plateau, but during the dry season they move to the Dallol Bosso North (a sandy agricultural region with permanent water in numerous pools) and the regions of Loga and Dogondoutchi (Ciofolo 1995, 2002, Boulet *et al.* 2004). In 1996, five Giraffes were observed in the Ansongo-Menaka Partial Faunal Reserve in Mali, on the border of Niger (Le Pendu & Ciofolo 1999, East 1999); however, this population is assumed to be extinct.

The Kordofan Giraffe is still present in N Cameroon, S Chad and Central African Republic (mainly Manovo–Gounda–St Floris N.P.). East

Giraffe *Giraffa camelopardalis* (see key opposite).

of this, there is a paucity of information, with no information available from Sudan, west of the Nile; they were eliminated from Radom N. P. and were not recorded at all from Southern N. P. or Shambe G. R. during recent surveys (Fay *et al.* 2007). Their main remaining nucleus is said to be Garamba N. P. in NE DR Congo (East 1999).

The Nubian/Rothschild's Giraffe survives in SE Sudan (in Boma N. P. and Bandingilo Reserve, but extinct in Dinder N. P. since 1985), SW Ethiopia, Uganda (Murchison Falls N. P. and Kidepo Valley N. P.) and Kenya, predominantly in protected areas; it is now extinct to the north and in Eritrea. The Reticulated Giraffe still occurs in S Somalia and Ethiopia, and occupies some of its historical range in N Kenya, mainly outside protected areas. Likewise, the Masai Giraffe also occupies parts of its historical range, although populations in Tsavo East N. P. in Kenya and Serengeti N. P. in Tanzania, as well as other protected and unprotected areas, have suffered declines; Masai Giraffe have been introduced to Rwanda (East 1999). Thornicroft's Giraffe is still found in large numbers in the Luangwa Valley of Zambia (East 1999).

Having been reintroduced to many parts of the range from which they were eliminated, Angolan and Southern Giraffes are currently common both inside and outside a number of protected areas in Namibia, Botswana, Zimbabwe and South Africa. In Angola, the Giraffes that historically occurred in the south-west of the country had disappeared completely by the 1940s, while the population in the south-east is now assumed to be extinct (Crawford-Cabral & Veríssimo 2005). East (1999) reported that the Angolan Giraffe still survived in small numbers in Sioma Ngwezi N. P. in SW Zambia. In Mozambique, a few individuals of the Southern Giraffe still occur in Coutada 16, adjacent to Kruger N. P. (J. Anderson pers. comm.).

Giraffe have been introduced to Swaziland with stock from South Africa and Namibia (although Namibian animals have done poorly; see Monadjem *et al.* 2003), and have also been introduced to a number of reserves in South Africa, including in KwaZulu-Natal and the Eastern Cape.

Habitat Giraffes are typically associated with *Acacia*, *Commiphora* and *Combretum* savannas. They occur marginally in the miombo *Brachystegia* woodland, while an isolated population (*G. c. thornicrofti*) occurs in the Luangwa Valley (where mopane, *Acacia* and *Combretum* are widespread), and in the *Isoberlina* woodland in Cameroon. Giraffes are today absent from true deserts and from rainforests; they also are absent from coastal savannas and large savanna mosaics (such as Lopé, in Gabon). Nevertheless, in NW Namibia they reside throughout the northern Namib Desert, where annual rainfall is less than 100 mm; here, they are amongst the best adapted ungulates in this desert environment (Scheepers 1992, Fennessy 2004). Giraffes in the northern Namib Desert rely on the riparian forests along the banks of ephemeral rivers, which include *Acacia*, *Faidherbia*, *Combretum* and *Commiphora* species, and surrounded by open gravel plains and sand dunes (Fennessy 2004).

East of the Nile, in S Sudan, Giraffes are never found in the permanently flooded areas of the Sudd, but aerial surveys (Mefit-Babtie 1983) showed that they were widely distributed over the entire floodplain throughout the year. During the height of the flood season, Giraffes were relatively few in the better drained woodlands yet, paradoxically, showed a perceptible seasonal preference for quite deeply flooded areas close to the permanent swamps. Observation revealed that the attraction for Giraffes at this time was vegetation growing on large termite

mounds, which are exceptionally abundant in the seasonally flooded grasslands (or 'Toic') and provide islands of soil raised above the surrounding floodwaters (J. Kingdon pers. comm.). In addition to climbers, such as *Ipomea*, the foliage of *Balanites*, *Acacia*, *Cassia*, *Grewia* and *Ziziphus* trees are all in an actively growing state at this time.

Freezing temperatures coupled with wind and rain can kill Giraffes (Dagg & Foster 1982); however, they can tolerate temperatures in excess of 40 °C (e.g. in Namibia and Niger). Spatial and temporal environmental factors, e.g. rainfall, affect their distribution as well as influence their seasonal movements. In Niger, Giraffes aggregate during the wet season where forage resources are limited (Le Pendu & Ciofolo 1999), while in East Africa, they commonly disperse during the wet season, aggregating near rivers in the dry season (e.g. Leuthold & Leuthold 1978a, Estes 1991a).

Abundance East (1999) estimated the total population at about 140,000 animals, predominantly in areas dominated by *Acacia* woodlands and shrublands, including 3500 Niger and Kordofan Giraffes (*peralta* and *antiquorum* combined), approximately 500 Nubian/Rothschild's Giraffes, 36,000 Reticulated Giraffes, 60,000 Masai Giraffes, 1200 Thornicroft's Giraffes (more numerous than at any time during the last 50 years) and more than 40,000 Angolan and Southern Giraffes (*angolensis* and *giraffa* combined). The most recent estimates put the total population at less than 100,000 animals (International Giraffe Working Group pers. comm.); efforts are underway to census the continent's populations more accurately (Fennessy 2007). The population in Niger (estimated to number 79 animals in 1999; Ciofolo *et al.* 2000) has since increased (Boulet *et al.* 2004, Suraud & Dovi 2006), with 193 animals photographed and identified in 2008 (Suraud 2009).

Giraffe density appears correlated with the distribution and density of high-quality forage: where appropriate food plants are abundant, Giraffes can live at densities of up to 2.6/km² (Pellew 1983a, b, 1984b), although Pratt & Anderson (1982) reported extraordinarily high densities in the small Arusha N. P. (3.96 ind/km²). Across its range Giraffe densities can vary between populations with 0.7/km² observed in Kruger N. P. (Hirst 1975) and 0.85/km² in Lake Manyara N. P. (Van der Jeugd & Prins 2000). On the other hand, where the abundance of high-quality forage is scarce, densities are markedly lower: for example, in Southern N. P. in Sudan, where Giraffes probably no longer occur, the population density was estimated at 0.05/km² (0.03–0.1/km²) (Boitani 1981) and in Tsavo East N. P. at 0.2/km² (Leuthold & Leuthold 1978a). The lowest densities have been recorded in the desert-dwelling populations of Niger and Namibia (0.01/km²; Fennessy *et al.* 2003, Fennessy 2004).

Adaptations The Giraffe displays a range of remarkable physiological and morphological adaptations, many linked directly to its standing as the world's tallest animal, perhaps foremost of which is its long neck. The osteology of the neck has been studied by anatomists since Owen (1841). Brownlee (1963) summarized theories concerning its evolution, and more recent contributors include Solounias (1999), Mitchell & Skinner (2003) and Simmons & Altwegg (2010). As is the case in all mammals (except manatees *Trichechus* spp. and sloths *Bradypus* spp. and *Choloepus* spp.), there are seven cervical vertebrae. Solounias (1999) suggested that neck length could be attributed to the presence of an 8th cervical vertebra, but as this vertebra supports a rib it must

Giraffe *Giraffa camelopardalis*.

by definition be a T1 (Mitchell & Skinner 2003, Badlangana *et al.* 2009). In addition, it would seem that the role of articulation between the thoracic and cervical sections of the vertebral column normally performed by C7 is at least partially taken over by T1 (Mitchell & Skinner 2003). Elongation of the neck is the result of uniform lengthening of the entire cervical series, including C7 (Badlangana *et al.* 2009), which is not a foetal process but occurs after birth (van Sittert *et al.* 2010). The neck vertebrae have characteristically pronounced opisthocoelous (or ball-and-socket) joints. Backward retraction of the base of the cervical column (so that it emerges well behind the sternum) and upward bowing of the thoracic vertebrae permits the forelegs to carry a high proportion of the head and neck weight, creating the 'chesty' profile so typical of Giraffes.

The Giraffe has 14 thoracic vertebrae (as noted above, the first thoracic somewhat resembling a cervical vertebra), five lumbar vertebrae and four sacral, although a vertebra may be lost to the tail, which is variable, ranging from 12 to 20. The pelvis is shorter than in most other Pecora and the sacral region is shorter compared with some bovids. Other large species like African Buffalo *Syncerus caffer* and ox have shorter thoracic regions, with 13 vertebrae, a longer lumbar region and similar length sacral. Camels have 12 : 7 : 4, thus their lumbar region is longer than the Giraffe's and the thoracic shorter. The Okapi *Okapia johnstoni* has 24 in the ratio 14 : 5 : 5, thus the sacral region is longest. In terms of length of the cervical vertebrae relative to overall vertebral column length, the neck vertebrae of the Okapi comprise 35% of the total vertebral column, while those of the Giraffe comprise 54% (Badlangana *et al.* 2009). The Okapi is approximately 55% shorter in height at the shoulder than the Giraffe, about 1.65 m compared with 3 m (C. Spinage pers. comm.).

The spines of the thoracic vertebrae are markedly elongated, forming points of origin for some of the neck muscles and for the *ligamentum nuchae* (Mitchell & Skinner 2003). These spines also enlarge the purchase (and therefore the swing of the entire forelimb) for muscles attached to the shoulder blade, notably the trapezius and rhomboid. Hall-Martin *et al.* (1977b) estimated weight for the head and neck combined at about 250 kg, and leverage of such an extended mass is facilitated by several adaptations, including the thoracic spinous processes, the presence of a large and extensive frontal cranial sinus (adding volume, but not mass to the skull; see Badlangana *et al.* 2011) and a reduction in the size of ossicones, compared with some extinct shorter-necked giraffe species. Van Schalkwyk *et al.* (2004) noted that cervical vertebrae mass decreases towards the head (largely a result of the size of each vertebra as the density actually increases), indicating that the bulk of the head and neck weight is supported at the base and that the distal end of the neck and head is comparatively light and more manoeuvrable than would otherwise be the case.

Adaptations that reduce the mass and weight of the head and neck apply much less to adult ♂♂. Their principal intra-specific weapon is the head and its offensive/protective protuberances, which is swung by the neck like a pendulum (Owen 1841, Kingdon 1979). The sometimes violent 'necking' (see Social and Reproductive Behaviour) has a correlation with accumulations of secondary bone growth and heavier skull weight for ♂♂ (up to ~15 kg; Dagg 1965, Seymour 2001), which suggests that male rivalry has resulted in selection for greater head weights (Simmons & Scheepers 1996). Osteoblasts build up and reinforce ossicones, presumably under the influence of male hormones, but osteoblasts also become active in

direct response to trauma. In the latter case they plaster over cracked bones and, in response to bruising, form encrustations on the outermost margins of the frontal bones (which overhang and thus help protect the orbits) along the exposed bridge of the nose (forming lumps on the nasal bones) and, most prominently, on the topmost ridge of the occipital bone. Understandably, occipital or 'nuchal' knobs are often mistaken for 'ossicones' and such giraffes are often described as 'five horned'.

An interesting detail in male Giraffe skulls is the occasional occurrence of bony encrustations on only one side of the head, probably resulting from repeatedly striking with that side of the head (J. Kingdon pers. comm.); indeed, Lydekker (1904) described a subspecies (*cottoni*) from a single specimen citing an 'orbital horn' over the right eye. Males normally appear to be 'ambidextrous', but they also have a choice as to the direction in which they will deliver or absorb blows. When they first engage, the contestants can either stand side by side or face in opposite directions. In the side-by-side position, one fighter swings to the right, one to the left. In the second choice, the same side is involved in both animals. In a small sample of 13 contests, J. Kingdon (pers. comm.) observed six pairs facing in opposite directions, four with their right shoulders engaged, two with the left. It would be interesting to learn whether advantages or disadvantages could accrue for ♂♂ with a particular preference and if there are regional patterns of preference.

Mitchell & Skinner (2003) discussed the possible advantages conferred by height, including protection from predation, increased vigilance, an enlarged surface area for thermoregulatory heat loss, and, in ♂♂, sexual dominance and access to food. These authors considered that the hypothesis that Giraffe height evolved as a response to the advantages conferred by feeding height stratification holds true only for adult ♂♂. For example, Du Toit (1990a) compared preferred heights of Giraffes with Greater Kudu *Tragelaphus strepsiceros*, and found that Giraffes tended to feed at heights of 1.7–3.7 m (♂♂ feeding higher than ♀♀) and Greater Kudu at heights of about 1 m, and occasionally up to 2 m. Greater Kudu were, therefore, competitive with female (and young) Giraffes. Other dietary studies have noted that Giraffes frequently feed well below their maximum foraging height (Leuthold & Leuthold 1972, Pellew 1984a, Young & Isbell 1991). None the less, analysis of the feeding competition hypothesis suggests that a long neck confers at least some advantage when lower leaves of trees have been eaten by these shorter browsers (Cameron & du Toit 2007).

An alternative theory suggested by some authors (Churcher 1978, Simmons & Scheepers 1996) is that the long neck may have evolved in response to the sexual advantage it confers, with ♂♂ using their necks and heads to achieve sexual dominance. However, this 'necks for sex' theory was not supported by empirical data that showed that morphological differences between the sexes are minimal and that any differences that do exist can be accounted for by the larger realized mass of ♂♂ (Mitchell *et al.* 2009a, van Sittert *et al.* 2010; but see Simmons & Altwegg 2010). In reviewing these two primary competing hypotheses, Simmons & Altwegg (2010) noted that the main challenge for the competing browser hypothesis is to explain why Giraffes have remained about 2 m taller than competing browsers for over one million years given the costs involved, while the sexual selection hypothesis fails to account for the long neck of female Giraffe (even though they are shorter than ♂♂).

Giraffe *Giraffa camelopardalis rothschildi* head of subadult female.

Some (Wright 1871, Brownlee 1963) have suggested that the Giraffe's long neck evolved because it assists the detection of predators: Giraffes have excellent sight, and their auditory and olfactory senses are acute. They can detect danger and conspecifics from a greater distance than other savanna species and seem to stay in contact by sight at a distance of over one kilometre (especially in open environments) thanks to their height advantage (Dagg & Foster 1982). Predator avoidance may also explain the coat markings in Giraffe, which could serve as camouflage for calves during the hiding stage, as calves are vulnerable to high rates of predation during the first few months of life (Langman 1977) (see Reproduction and Population Structure). Social factors are a significant modifier of vigilance in Giraffes: in Kruger N. P., bulls scan the most when they are in groups with larger bulls and least when they are with smaller bulls. Conversely, predation risk does not appear to be a significant modifier of vigilance: cows do not change their vigilance behaviour when alone or accompanied by calves (Cameron & du Toit 2005).

In addition to the extension of the neck, there is also elongation of the limbs. However, the elongation of the limb bones is independent of a corresponding increase in their diameter. The more distal limb bones, particularly the metapodials, but not the humerus or femur, are extraordinarily elongated and slender for an animal of such size, suggesting that the increase in length must be compensated for by an increase in strength (Mitchell & Skinner 2003). The latter authors posited that this increase in strength was facilitated by the high density of the lower limb bones, such that about 80% of all skeletal calcium is in the leg bones, with the radius/ulna and metacarpal bone having the highest relative density of any bone at 150% and 178%, respectively. That the weight-bearing bones are denser than others is supported by the study of Van Schalkwyk *et al.* (2004), who also propose that, in addition to increased density, Giraffe limb bone strength is achieved by the bones being much straighter and having much thicker walls than in other artiodactyls. However, Van Schalkwyk *et al.* (2004) also presented evidence that the skeleton of the Giraffe is not unique with respect to bone density. Mitchell *et al.* (2005) have since shown that the Giraffe skeleton contains three times more absolute amounts of calcium and phosphorous than is found in the African Buffalo skeleton. This translates into a 1.5- to 2-fold higher calcium requirement for Giraffes, with which they seem to cope effectively by selecting for calcium-rich, dicotyledonous, browse. However, sources to meet phosphorous requirements are less obvious and a

seasonal deficiency of phosphorous is a probable cause of instances of observed osteophagia (see Foraging and Food).

Both neck and limb elongation requires an unusual cardiovascular and respiratory system. Physiological adaptations of the circulatory system have been investigated in detail by numerous authors (e.g. Amoroso *et al.* 1947, Lawrence & Rewell 1948, Goetz 1955, Goetz & Keen 1957, van Citters *et al.* 1966, Kimani 1983, Badeer 1986, 1997, Hargens *et al.* 1987, Kimani *et al.* 1991a, b, Pedley *et al.* 1996, Mitchell *et al.* 2006, 2008, 2009b). The hydrostatic pressure exerted by gravity on the column of blood in the neck (the heart is ~2 m away from the head; Mitchell & Skinner 1993) necessitates an average systemic blood pressure of ~200 mm Hg compared with the norm of 100 mm Hg in other terrestrial mammals (see Mitchell & Skinner 2009 and references therein). Although widely reported as having a very large heart relative to overall mass, heart mass in Giraffe is only 0.5% of body mass – the same as that in other mammals (Mitchell & Skinner 2009). Instead of cardiac enlargement or an increase in cardiac output, cardiac hypertrophy of the left ventricular and interventricular heart wall muscles (their thickness is linearly related to neck length) is the key to maintaining cerebral blood flow. Further, hypertrophy of the arteries and arterioles at or below the level of the heart helps control blood flow to the organs and, during drinking, the thick-walled arteries help prevent blood from rushing to the head (Mitchell & Skinner 2009). Valves in the jugular vein direct the large amounts of blood returning to the heart via the inferior vena cava into the right atrium, and prevent it regurgitating into the jugular (Mitchell *et al.* 2009b; contra Hargens *et al.* 1987). When a Giraffe raises its head, a momentary pause during head lifting and intense extracranial vasoconstriction helps to prevent fainting (Mitchell *et al.* 2008). Microcirculation haemodynamics, the thick skin and thickened arteries, an autonomic nervous system and innervation of the limbs help prevent oedema (Hargens *et al.* 1987, Pedley 1987).

Other physiological adaptations include an efficient nasal cooling system that regulates brain temperature (up to 3 °C lower than body temperature) and reduces respiratory water loss, while respiratory dead space volume is minimized by a variable diameter of the trachea (Mitchell & Skinner 1993). Whole body thermoregulation might be passively maintained by skin patches acting as heat dissipating windows facilitated by vasodilation of the blood vessels beneath the dark skin surface (Mitchell & Skinner 1993, 2004). In Etosha N. P., Namibia, Giraffes have been observed to face the sun when the temperature is high, probably in order to diminish the surface exposed (Kuntzsch & Nel 1990).

Many of the extant Giraffe's adaptations are essentially those of a very large animal not just a very tall one. While their height has facilitated several detailed physiological adaptations, their size also increases nutritional demands. For example, ♂♂ require some 20 g of calcium per day; by comparison, a human weighing one-tenth the weight of a giraffe has a daily calcium requirement of one-fortieth (Mitchell & Skinner 2003). In order to fulfil their daily nutrient requirements, Giraffes must consume a large amount of browse in the form of legumes. Their molars are heavy, brachydont and selenodont. The lower incisors combine with the bi- or tri-lobed canines to form an arc to comb the leaves and bend/break the thorns off shoots. Horny papillae help protect the lips and tongue from thorns, and thick saliva protects the tongue and buccal cavity.

Giraffe *Giraffa camelopardalis* myology of head.

The tongue is long and mobile, up to 45 cm, allowing the Giraffe to precisely select food items. Although Giraffes drink when water is available, they can survive for a long time without water. In the north of the Namib Desert, Scheepers (1992) observed Giraffes drinking twice during the course of six years of observation, and J. Fennessy (pers. comm.) only ten times during a five-year study period. Giraffes seem to demonstrate a total lack of dependence on available bodies of water and get their water from preformed water in food and dew on the plants (Scheepers 1992, Fennessy *et al.* 2003, Fennessy 2004). A gall bladder may or may not be present.

Giraffes present a biphasic activity budget: energy consumptive activities like feeding and walking occur more post-dawn and pre-dusk, while energy conserving activities such as resting and ruminating occur more during the hottest period of the day (Leuthold & Leuthold 1978b, Pellew 1984a, Fennessy 2004, 2009).

Contrary to most other quadrupeds, Giraffes swing both legs on the same side at almost the same time during their 'pacing' walk (this pattern of limb movement is abandoned when the Giraffe breaks into a gallop). A galloping Giraffe can reach 56 km/h, young running faster than adults. Their long legs enable them to clear fences 1.5 m in height (Dagg & Foster 1982).

Giraffes emit a scent that can be detected by keen-nosed humans over considerable distances. Wood & Weldon (2002) analysed extracts of hair samples from adult Reticulated Giraffe ♂♂ and ♀♀ and found two highly odoriferous compounds (as well as a number of other major compounds) that appeared to be primarily responsible for the Giraffe's strong scent. They suggested that these compounds may deter microorganisms or ectoparasitic arthropods, as most of these compounds are known to possess antibacterial or fungistatic properties against mammalian skin pathogens or other microorganisms. The levels of p-cresol, one of the compounds detected, in Giraffe hair are sufficient to repel some ticks.

Foraging and Food Giraffes are selective browsers, feeding predominantly on leaves and buds on trees and shrubs. *Acacia* species form the bulk of their diet throughout their range, as well as species of the genera *Balanites*, *Commiphora*, *Detarium*, *Boscia*, *Combretum*, *Ziziphus* and *Grewia*. However, many other species are eaten: at least 25 in Willem Pretorius G. R., South Africa (Kok & Opperman 1980), 29 in the Hoanib R. region, N Namibia (Fennessy 2004), 45 in Serengeti N. P. (Pellew 1984a) and in Niger (Ciofolo & Le Pendu 1998), 69 in Tsavo East N. P. (Leuthold & Leuthold 1972) and 77 in the Middleveld of Zimbabwe (Lightfoot 1978). Seasonally, they feed

on a range of species and plant parts, including herbs (e.g. *Hibiscus asper*) and climbers and vines (species of the genera *Ipomea*, *Cissus*). The proportion of grass species in the diet is very low.

Giraffes are highly selective with regards to the plant's growth stage and phenology. The diet varies according to the season, influenced by the availability of plant species and their growth stage (Hall-Martin 1974, Ciofolo & Le Pendu 2002, Fennessy 2004). Across their range this involves small-scale seasonal movements: in southern and East Africa, Giraffes often feed on deciduous trees, shrubs and vines during the wet season, and on evergreen species, near streams and rivers, during the dry season (Leuthold & Leuthold 1972, Kok & Opperman 1980). In N Tanzania, the ♂♂ move to key resource areas during the dry season (Van der Jeugd & Prins 2000). In West Africa they feed on the shrubby acacias in the tiger bush during the wet season, and on the woody species of a sandy agricultural region in the dry season (Ciofolo & Le Pendu 2002). Pellew (1984a) found that the diet of adult ♀♀ was nutritionally richer than that of bulls that consumed significantly higher proportions of fibres and lignin; furthermore, species-selection and the nutritional quality of diet were not obviously related and energy budgets suggest that Giraffes can maintain a positive energy balance during most stages of the female reproductive cycle (Pellew 1984c). In Niger, nursing ♀♀ seem to avoid high levels of tannins even though it means giving up the high-quality forage preferred by the ♂♂ (Caister *et al.* 2003), while in N Namibia ♀♀ avoided areas of human populations and thus forego richer nutrient food sources in preference for safety (Fennessy 2004).

Pellew (1983a) demonstrated that, when Giraffes are not too numerous, their impact can actually stimulate shoot production in *Acacia* species, which soon declined when the browsing stimulus was withdrawn. Young & Okello (1998) experimentally excluded Giraffes and Savanna Elephants *Loxodonta africana* from access to *Acacia*, thereby reducing consumption of new shoots of the higher branches by 63%, which also induced the growth of longer spines. Pellew (1983a) suggested that *Acacia* species have evolved a high resilience to browsing.

LEFT: Twigs of *Acacia drepanolobium* before and after Giraffe *Giraffa camelopardalis* browsing (plus gall ants).

RIGHT: Giraffe *Giraffa camelopardalis* tongue pulling twig into mouth (from film).

Coe (1998) found that the pods of *A. eriobola* were significantly larger above the browse-line for those trees that had been exposed to Giraffe feeding. In Ithala G. R. (South Africa), some *Acacia* species such as *A. caffra* and *A. karoo* showed high mortality attributable to Giraffe browsing while others including *A. tortilis* did not seem to be affected (Bond & Loffell 2001). In Kruger N. P., Giraffes were highly destructive and detrimental to the overall fecundity of *A. nigrescens* during the season examined (Sep), resulting in a significantly reduced fruit set at heights accessible to Giraffes (Fleming *et al.* 2006).

Carnivorous ants that are symbiotic with some *Acacia* species reduce the amount of time that young Giraffes can spend browsing on any one plant (Madden & Young 1992). On the other hand, *Acacia* seed consumption by Giraffes favours seed dispersal into non-shaded habitats and enhances the potential for seed germination because digestion processes decrease seed infestation by bruchids (Miller 1994, 1996). It has also been suggested that Giraffes play a role in pollination; for example, Du Toit, J. T. (1990b, 1992) posited that Giraffes in Kruger N. P. may be providing a pollination service for *Acacia nigrescens*, although empirical evidence suggests that Giraffes are only flower predators (Fleming *et al.* 2006).

Giraffes sometimes lick soil near termite mounds and chew bones (osteophagia) (Western 1971, Wyatt 1971, Leuthold & Leuthold 1972, Hall-Martin 1975, Ciofolo & Le Pendu 1998). Although Western (1971) maintained that this behaviour was unlikely to appreciably offset any mineral deficiency, Langman (1978) suggested that osteophagia might mitigate seasonal deficiencies or imbalances in calcium, phosphorus and/or magnesium, and Mitchell *et al.* (2005) predict that bone chewing may be a response to phosphorous deficiencies. Nesbit Evans (1970) also observed a Giraffe eating the stomach contents of a Common Eland *Tragelaphus oryx* carcass, and Western (1971) reported them scavenging on the carcass of a Grant's Gazelle *Nanger granti*.

Feeding is the dominant diurnal activity of Giraffes and differs significantly between sexes, season and populations. Females spend more time feeding than ♂♂ in Serengeti N. P. (72% cf. 55%; Pellew 1984a) and in Tsavo East N. P. (Leuthold & Leuthold 1978b), while bulls spend more time feeding in N Namibia: 59% cf. 51% (Fennessy 2004). In Lake Manyara N. P., solitary ♂♂ spent more time feeding than ♂♂ in groups; Giraffes on average spent only 35% of their time on browsing (Van der Jeugd & Prins 2000). In Niger, time spent browsing doubles during the dry season compared with the wet season: 46% cf. 23%, respectively, probably due to variation in forage quality and its spatial distribution (Ciofolo & Le Pendu 2002). The other principal diurnal activities are walking, resting, ruminating and, to a lesser extent, vigilance. According to Ginnett & Demment (1997), there is no sex difference in rumination time but ♂♂ spend more time in activities other than foraging and rumination, such as walking. Giraffes are also active at night, but feed significantly more during moonlit nights (34% cf. 22%, ♂♂ versus ♀♀, respectively) and ruminate more during dark nights (49% cf. 40%, ♂♂ versus ♀♀, respectively) (Pellew 1984a).

Social and Reproductive Behaviour Giraffes are sociable, but herd composition is fluid, unstable and highly variable, comprising any combination of sex and age classes at any given time and rarely consisting of the same individuals for any length of time (e.g. Pellew 1984b, Le Pendu *et al.* 2000, Van der Jeugd & Prins 2000, Fennessy 2004). Mean herd sizes are varied, often ranging between 2.6 and 8

Giraffe *Giraffa camelopardalis* mating behaviour.

(Dagg & Foster 1982), depending on population density and food availability: Katavi N. P. (Tanzania), 3.6 (Caro 1999a), Luangwa Valley, 3.6 (Bercovitch & Berry 2010; and see Berry 1973), NW Namibia, 3.8 (Fennessy 2004), Tsavo East N. P., 4.1 (Leuthold, B. M. 1979), Lake Manyara N. P. (Tanzania), 4.8 (Van der Jeugd & Prins 2000), and Niger, 6.9 (Y. Le Pendu & I. Ciofolo unpubl.). Maximum herd size also varies between populations (for example, from 13 to 47), although as many as 240 individuals have been observed in a herd (Pellew 1983b). Males tend to be solitary or associate in bachelor herds, becoming increasingly solitary as they mature, and often wandering between herds monitoring the reproductive status of ♀♀.

Giraffes are not territorial, but occupy home-ranges that vary in size according to sex/age classes, competition, forage and resource availability (Leuthold & Leuthold 1978a, Le Pendu & Ciofolo 1999, Van der Jeugd & Prins 2000). In Tsavo East N. P., male and female mean home-range sizes were very similar (164 km² and 162 km², respectively), but smaller during the dry season than during the wet season (Leuthold & Leuthold 1978a). Seasonal home-ranges were exclusive in Niger where their mean size during the dry season (90.7 km²) was twice as large as that during the wet season (46.6 km²). Other mean annual home-range sizes recorded for adult ♀♀ (using minimum convex polygon method) were 41 km² in Timbavati Private N. R., South Africa (Langman 1973), 68 km² in the Luangwa Valley (Berry 1978), 200 km² in N Namibia (Fennessy 2009), 285 km² in Kruger N. P., South Africa (du Toit 1988) and 367 km² in Niger (Ciofolo & Le Pendu 1998). Home-ranges recorded for ♂♂ are: 37 km² in Timbavati Private N. R. (Langman 1973), 82 km² in Luangwa Valley (Berry 1978) and 842 km² in Niger (Ciofolo & Le Pendu 1998). The largest home-ranges recorded for ♂♂ are for animals living in desert-dwelling populations: 1950 km² and 1627 km² for two bulls in N Namibia (Fennessy 2009) and 1564 km² in Niger (Le Pendu & Ciofolo 1999); the largest cow home-range reported was also in Niger (1379 km²; Le Pendu & Ciofolo 1999). Giraffes in Niger have been observed to exhibit the longest range of movement,

up to 300 km (Le Pendu & Ciofolo 1999). The longest linear range of movement measured in other populations was 86 km in the Luangwa Valley (Berry 1978), 70 km in N Namibia (Fennessy 2009) and 50 km in Tsavo East N. P. (Leuthold & Leuthold 1978a). The mean daily linear movements of two adult bulls (equipped with a GPS satellite collar) in N Namibia varied between 4.3 and 7.5 km (Fennessy 2009).

Males exhibit flehmen when testing the reproductive status of ♀♀. If the ♀♀ are receptive, dominant ♂♂ actively pursue and fend off competitors. Often such behaviour results in 'necking' bouts, which are assumed to be dominance-driven (Coe 1967). Males with thicker, longer necks appear dominant during violent necking encounters with other ♂♂, and subsequently are more successful in courting ♀♀ (Pratt & Anderson 1982, 1985, Simmons & Scheepers 1996). Serious fights are rare, but when observed they have been brief and violent; Downey (in Kingdon 1979) saw one bull concussed during one such fight, whereupon the fallen animal was hammered with both head and hooves while lying prostrate. Dagg & Foster (1982) also reported an instance where a bull was knocked unconscious and took 20 minutes to recover. Association between adult ♂♂ was random in Lake Manyara N. P., but ♀♀ showed clear non-random association (Van der Jeugd & Prins 2000).

The ♂ follows the oestrous ♀ closely, sometimes resting his head on her rump and/or butting her gently with his horns. Males exhibit lauschlag (the ♂ tapping between or alongside the hindlegs of the ♀ with his forelegs), causing the ♀ to move slightly forward. During copulation the bull stands with head held high, mounting by sliding his forelegs loosely onto her flanks, and then standing bolt upright while at the same time delivering an ejaculatory thrust that also moves the cow forward (Estes 1991a).

Females usually leave the herd to calve. Young are born while the cow is still standing, her back legs slightly bent so as to lessen the fall, which, at two metres in height results in the breakage of the umbilical cord. Calves may stand within half an hour. Lightfoot (in Van Aarde 1976) observed that a Giraffe made no attempt to eat the placenta after giving birth, although Dagg & Foster (1982) and Kristal & Noonan (1979) noted otherwise. Kok (1982) described a free-living Southern Giraffe ♀ scavenging on her dead recently born calf. The mother showed intense interest in the carcass over a period of weeks, no doubt indicative of the mother–calf bond.

Neonates are hidden for a few weeks and thereafter form nursery groups only in populations where feeding and drinking resources are distant from place of birth (Langman 1977, Pratt & Anderson 1979). Mothers and young remain strongly associated for 14–22 months, until around the time of the next parturition (Pratt & Anderson 1982). Young calves are playful and peaceful, but frequent 'necking' occurs between subadult ♂♂.

Vocal folds and laryngeal ventricles are entirely absent, supporting the view that Giraffes are mute (Owen 1841, Hahn & Mayhew 1999). Nevertheless, they infrequently emit various loud sounds, notably under stressful conditions. They can grunt, snort, cough and whistle, and the calves bleat, though what such vocalizations communicate remains undetermined (Dagg & Foster 1982). Captive Giraffes emit infrasonic vocalizations around or below 20 Hz (von Muggenthaler *et al.* 1999). Bashaw (2003) undertook efforts to demonstrate the communicative function of these vocalizations in captive Rothschild's Giraffes by submitting playbacks of infrasonic vocalization; however, this initial work showed no evidence of Giraffes modifying their behaviour.

Reproduction and Population Structure Giraffes breed throughout the year, although birthing peaks have been observed in numerous populations, including: Nairobi N. P. in Kenya (Aug and Sep; Foster & Dagg 1972), Waza N. P. in Cameroon (Nov–Jan, when *Acacia seyal* is flowering; Ngog Nje 1983), Serengeti N. P. (Sep; Sinclair *et al.* 2000) and in N Namibia (Dec; Fennessy 2004), and at different times of the year in the same area (such as Kruger N. P.; see Dagg 1971). Birthing peaks often correlate with rainfall (Hall-Martin *et al.* 1975) and seem to coincide with the production of new *Acacia* shoots that have a high protein content (Sinclair *et al.* 2000, Fennessy 2004). Van der Jeugd & Prins (2000) suggest that differences in ecological circumstances create variability in mating strategies. Giraffes in captivity also breed aseasonally (Backhaus 1961, Bercovitch *et al.* 2004).

A single calf is born, although twins have been recorded (Dagg & Foster 1982, R. Brenneman pers. comm.). Mean gestation period is approximately 457 days or 15 months (Backhaus 1961, Skinner & Hall-Martin 1975, Dagg & Foster 1982); one individual in captivity gave birth to consecutive infants only 420 days apart (Bercovitch *et al.* 2004).

Neonates are heavier in the wild (101 kg) compared with those in captivity (55 kg, Skinner & Hall-Martin 1975). The mean height at birth is 1.8 m and 1.9 m for ♀♀ and ♂♂, respectively (Pellew 1983b). Calves nearly double their height within the first year (Pratt & Anderson 1982), which probably serves as an anti-predator strategy because calves are extremely vulnerable to predation (Estes 1991a; see later). Giraffe milk is rich in fat (13–17%), protein (6%) and ash content, although lactose concentration is lower than in bovine milk (Aschaffenburg *et al.* 1962, Hall-Martin *et al.* 1977a, Dagg & Foster 1982). In the wild, Pratt & Anderson (1979) found that male and female calves suckle at the same rate. Timing of weaning varies: exceptionally as long as two years, but typically around 9–12 months, although calves are able to eat solid food after the third or fourth week and begin ruminating at between three and four months (Langman 1977, Dagg & Foster 1982).

Calving intervals are 19–20 months (Hall-Martin & Skinner 1978, Dagg & Foster 1982, Pellew 1983b, Ciofolo *et al.* 2000, Bercovitch & Berry 2009). Intervals are similar in captivity ($n = 61$), with a range of 14–38 months (Bercovitch *et al.* 2004). The interval between parturition and conception is usually 4–9 months. First conception has been recorded at 50 months in Serengeti N. P. (Pellew 1983b) and 56 months in southern Africa (Hall-Martin & Skinner 1978). In captivity, average age at first parturition was 57 months ($n = 12$; Bercovitch *et al.* 2004). Males are sexually mature at 3.5 years of age (and even earlier in captivity), but in the wild are probably excluded from reproduction by older bulls (Hall-Martin *et al.* 1978).

Adult sex ratios have been recorded as being female-biased in Serengeti N. P. (Pellew 1983b), Nairobi N. P. (Dagg & Foster 1982), Katavi N. P. (Caro 1999a), Luangwa N. P. (Berry 1973) and in Niger (Ciofolo *et al.* 2000), while the opposite was true in Tsavo East N. P. (Leuthold & Leuthold 1978a). In N Namibia, sex ratios differed between subpopulations, although was unbiased across the overall population (Fennessy *et al.* 2003, Fennessy 2004). Sex ratio at birth is 1 : 1 (Dagg & Foster 1982, Bercovitch *et al.* 2004, Bercovitch & Berry 2009). Limited research restricts any real assessment of such variation.

Between 54% and 62% of a given population is more than four years old. Mortality rates are strongly shaped by Lion *Panthera leo* predation, especially on neonates. In Serengeti N. P., 58% of young Giraffes died during their first year of life while only 2% died at the

Neck-sparring and fighting in male Giraffes.

age of four (Pellew 1983b); this is slightly lower than the figure of 75% given by Foster & Dagg (1972) for the same general area. In Kruger N. P., first-year mortality was also high at 48% (Hall-Martin 1975). A breeding ♀ in Luangwa gave birth at 24 years of age (Bercovitch & Berry 2009), and these authors suggest that lifetime reproductive success (which ranged as high as 11 in Luangwa) is more dependent on longevity and calf survivorship than on reproductive rate. The maximum lifespan of male Giraffes, based on individuals in Luangwa Valley, is shorter (22 years) compared with ♀♀ (28 years) (Berry & Bercovitch 2012); maximum longevity in captivity is recorded at 39 years (Weigl 2005).

Given the uniform sex ratio at birth, comparable mortality rates, suckling rates and inter-birth intervals among juveniles, and the similar growth rate of calves while nursing, Bercovitch *et al.* (2004) suggest that adult ♀♀ invest equally in their offspring, regardless of sex, and that ♂♂ surpass ♀♀ in size only after the period of dependency.

Predators, Parasites and Diseases Lions are the main predator (Pienaar 1969a, Pellew 1983b, Hayward & Kerley 2005), although Giraffes are formidable opponents with their long strong legs and hooves; reports of Lions killed or injured by Giraffes are not uncommon. Spotted Hyaenas *Crocuta crocuta*, African Wild Dogs *Lycaon pictus* and Leopards *Panthera pardus* (Scheepers & Gilchrist 1991) have been reported preying on calves occasionally, while observations of Nile Crocodile *Crocodylus niloticus* and Cheetah *Acinonyx jubatus* kills have also been recorded.

Ectoparasites are particularly numerous around the anus and the genitalia. Common tick species recorded from animals in southern Africa include *Amblyomma hebraeum*, *Boophilus decoloratus*, *Hyalomma aegyptium*, *H. marginatum*, *H. truncatum*, *Rhipicephalus appendiculatus*, *R. camelopardalis*, *R. evertsi* and *R. longiceps* (Horak *et al.* 1983c, 1992a, 2007). Helminth parasites include: *Cooperia pectinata*, *C. punctata*, *Fasciola gigantica*, *Haemonchus contortus*, *H. mitchelli*, *Moniezia expansa*, *M. nullois*, *Monodontella giraffae*, *Parabronema skrjabini*, *Pseudofilaria giraffae*, *Setaria labiatopapillosa*, *Skrjabinema* sp., *Trichocephalus gracilis*, *Trichuris globulosa*, *T. giraffae*, *Trichostrongylus* sp. and *Echinococcus* sp.

(Dagg 1971, Boomker *et al.* 1986, Krecek *et al.* 1990; and references therein). Bengis *et al.* (1998) recorded three species of *Sarcocystis* from muscle fibres of a Giraffe in South Africa (*Sarcocystis giraffae*, *S. klaseriensis* and *S. camelopardalis*). Larvae of the oestrid fly *Rhinoestrus giraffae* have been collected from Giraffes (Laurence 1961).

Giraffes are vulnerable to anthrax, gastroenteritis and rinderpest, the latter killing 40% of the Giraffes in N Kenya in 1960 (Dagg 1971 and references therein). Other recorded parasite-induced diseases include listeriosis (Cranfield *et al.* 1985) and brucellosis (Jensen 1999). Polyarthritis and polyosteomyelitis were recorded in a juvenile (Jacobson *et al.* 1986), while a case of Mycoplasma-associated polyarthritis was recorded in a captive Reticulated Giraffe (Hammond *et al.* 2003). Various skin diseases and lesions have been observed.

Conservation IUCN Category: Least Concern (*G. c. peralta* – Endangered D; *G. c. rothschildi* – Endangered C2a(i)). CITES: Not Listed.

East (1999) estimated the total number of Giraffes in Africa to exceed 140,000 (of which 40% were in or around protected areas and private lands); such numbers were thought capable of being maintained were they adequately protected (East 1999). Current estimates put the population at less than 100,000, evidencing declines in some populations. For example, poaching and armed conflict across the range of the Reticulated Giraffe in Somalia, Ethiopia and Kenya has reduced numbers to perhaps fewer than 3000 individuals (Georgiadis, in Fennessy 2007). Smaller, managed populations have also declined: a decline in Lake Nakuru N. P. in Kenya has been attributed to dietary complications from highly concentrated tannin levels because of forced overconsumption of the park's declining acacia trees, which may have compromised young Nubian/Rothschild's Giraffe, making them easy and opportunistic prey for the park's Lion population (Brenneman *et al.* 2009).

Important safety havens include Waza N. P. and the hunting zones of North Province in Cameroon, Zakouma N. P. (Chad), Murchison Falls N. P. (Uganda), Boma N. P. (Sudan), Omo N. P. (Ethiopia), South Luangwa N. P. (Zambia) and, in southern Africa, Etosha N. P. (Namibia), Hwange N. P. (Zimbabwe) and Kruger N. P. (South Africa). Masai Giraffes occur widely both within and outside protected areas in Kenya and Tanzania, but represent a vestige of their former numbers and range. Small numbers of Nubian Giraffes have been introduced to smaller parks and game reserves in Kenya, including Lake Nakuru and Ruma National Parks, while both Angolan and Southern Giraffes have been widely reintroduced and introduced in southern Africa. Giraffes were also introduced to Akagera N. P. in Rwanda in 1986 (East 1999).

In Niger, conservation development projects have facilitated the Niger Giraffe's population increase in an area outside any formal protected park or reserve. None the less, poaching and habitat loss, fragmentation and degradation as a result of increased aridity, and expansion of human activities continue to impact on the Giraffe's distribution. This small population survives only in the wild, since the Giraffes held in captivity in the Vincennes Zoo, France, which were long referred to as *peralta*, in fact belong to the subspecies *antiquorum* (Hassanin *et al.* 2007).

The recently uncovered genetically distinct populations clearly represent evolutionarily significant units that are highly threatened and lack appropriate recognition in current management plans (Brown *et al.* 2007).

Measurements*Giraffa camelopardalis*

TL (♂♂): 5.05 (4.86–5.27) m, n = 15

TL (♀♀): 4.44 (4.16–4.75) m, n = 16

Sh. ht (♂♂): 3.31 (3.13–3.47) m, n = 15

Sh. ht (♀♀): 2.80 (2.72–2.92) m, n = 16

WT (♂♂): 1191.8 (973–1395) kg, n = 18

WT (♀♀): 828.4 (703–950) kg, n = 18

South Africa (from individuals older than eight; Hall-Martin 1975)

Mitchell *et al.* (2009a) reported an upper weight for ♀♀ of 1049.2 kg and 1511.6 kg for ♂♂**Key References** Ciofolo & Pendu 1998; Dagg 1971; Dagg & Foster 1982; Fennessy 2004; Hall-Martin 1974, 1975; Hall-Martin *et al.* 1975, 1978; Leuthold & Leuthold 1972, 1978a, b; Mitchell & Skinner 1993, 2003, 2009; Pellew 1983a, b, 1984a, b; Pratt & Anderson 1979, 1982.**Isabelle Ciofolo & Yvonnick Le Pendu****Subfamily OKAPINAE – Okapi**Okapinae Bohlin, 1926. *Palaeontologia Sinica*, ser. C, 4: 1–179.Subfamily Okapinae is a monotypic subfamily, represented by a single species, the Okapi *Okapia johnstoni*.**GENUS *Okapia*****Okapi***Okapia* Lankester, 1901. *Nature* 64: 24.

The genus *Okapia* includes only the Okapi *Okapia johnstoni*, which is confined to lowland rainforest in DR Congo. The only confirmed fossil record for the species is an early Pliocene ossicone (Cooke & Coryndon 1970). The Okapi exhibits a number of primitive and conservative morphological and behavioural traits. It has been referred to as a living fossil by some authors (Joleaud 1937, Colbert 1938) and some have aligned it with the extinct Palaeotraginae (McKenna & Bell 1997).

Okapia differs from *Giraffa* in being much smaller, as little as one-third the mass, with proportions more like those of other ruminants of similar size; its cervical vertebrae are not elongated, there are five sacral vertebrae (cf. usually four in *Giraffa*) and neck and limbs are only moderate in length. Its 'horns' (ossicones) are hair-covered, situated above the eyes, in ♂♂ only and there is no median ossicone. The skull is elongated, the long braincase in line with the facial part of skull and not flexed.

Peter Grubb***Okapia johnstoni* OKAPI**

Fr. Okapi; Ger. Okapi

Okapia johnstoni (Sclater, P. L., 1901). *Proc. Zool. Soc. Lond.* 1901 (1): 50. DR Congo, 'in sylvis fluvio Semliki adjacentibus' (= Semliki Forest, Mundala).

Taxonomy Monotypic. The discovery and naming of this species is one of the great epics of natural history as well as a vivid illustration of the power of preconceived ideas. While the explorer H. M. Stanley was in the Ituri Forest in 1876 he saw pieces of striped skin, which his interpreters told him came from a type of 'forest donkey'. This unknown animal caught the interest of his friend and admirer, the naturalist, Sir Harry Johnston, who, around the turn of the century, was Governor of Uganda. When the opportunity arose, Johnston visited Ituri and, for a time, thought he was on the trail of the extinct three-toed *Hipparion*. Disbelief in the Okapi's two-toed tracks, together with an attack of malaria made Johnston abandon his quest, but he carried away two hide bandoliers cut from the haunches of Okapis. These were sent to the anti-Darwinian, P. L. Sclater, who provisionally assigned them to the genus *Equus*, naming the new species *Equus johnstoni*. In early 1901 Johnston was sent an entire skin and two skulls

of Okapis by a Swedish agent of the Congo Free State, Lieutenant Karl Eriksson, and immediately realized that the animal was an ally of the Giraffe *Giraffa camelopardalis*. He sent the skin, skulls and his own brilliant pictorial reconstructions of the living animals to Sir Edwin Ray Lankester, Director of the British Museum of Natural History. Latinizing the Mbuti pygmy name into *Okapia*, he described *Okapia johnstoni* in the journal *Nature* in the same year that Sclater's *Equus johnstoni* came out in the slow-to-be-published *Proceedings of the Zoological Society of London*.

Synonyms: *erikssoni*, *kibalensis*, *liebrechtsi*, *tigrinum*. In contrast to Giraffes, which have only 30 chromosomes, the chromosome number of the Okapi recorded from animals in captivity is either 2n = 46, 2n = 45 or 2n = 44 (Ulbrich & Schmitt 1969, Hösli & Lang 1970, Koulischer 1978, Petit *et al.* 1994, Vermeesch *et al.* 1996, Petric 2004a); the 2n = 45 karyotype has been recorded from at least one wild-caught

Okapi *Okapia johnstoni*.

♂ (Petit & de Meurichy 1986), and has occurred in 53 of 116 captive animals examined (K. Leus pers. comm.). This aneuploidy was likely established through a Robertson fusion. These animals appear normal and produced viable offspring (Lindsey *et al.* 1999).

Description A small forest giraffid that may, in some postures, appear strikingly deer-like, with a narrow, long-muzzled head, short, muscular, tapered neck and posteriorly sloping back. The Okapi's bilobed lower canines and hair-covered horn formations originating from epidermal cartilaginous ossicones are features it shares uniquely with all other living and fossil giraffids. The Okapi shares with the Giraffe a distinctive lateral pacing gait in which the weight is momentarily shared by legs on the same side of the body as the animal progresses. The Okapi also differs in having cervical vertebrae that are not elongated; there are usually five sacral vertebrae in the Okapi (cf. four in the Giraffe), and only ♂♂, generally, have ossicones.

The Okapi is a distinctively coloured and patterned animal. Face pale grey, variably grizzled with dark hairs. Crown chestnut brown with fur-covered, posteriorly oriented, bone-tipped 'horns' (see below), although the hair on the tips is sometimes rubbed to the bone. Eyes dark brown, set off by long lashes. Ears large, chestnut brown, with a black fringe of hairs. Neck and body overall dark chestnut brown with maroon overtones. Chest and upper abdomen chestnut brown, lightening and becoming nearly white in the perineal region. Hindquarters dark brown to black with 18–25 or more irregular white horizontal stripes, extending over the buttock and gaskin (tibia) in a pattern that is unique to each animal. Rear cannon or metatarsus white with a black band on the fetlock and white pastern. Similar, though reduced pattern, occurs on the upper forelegs. Fore cannon, or metacarpus, white, with a brown to blackish line running up the front, black hair on the knee and fetlock, white pastern. Tail chestnut brown with black tuft, reaching to the level of the hocks. Young Okapis have patterning similar to adults, but with overall more shaggy pelage, and a distinct blackish mane from the base of the head along the upper back, which gradually diminishes as the animal grows older and all but disappears by 12–14 months. Hooves

rounded and relatively small for the size of the animal. The pelage is short and lightly oiled from a reddish-brown secretion from the skin that accumulates abundantly in the ears, and renders the pelage somewhat water-resistant. Unlike Giraffes, both sexes have large pedal glands above all four hooves (larger in the fore hooves; Pocock 1936). These drain around the top of the hoof in a channel that leads down between the two toes. Adult ♀♀ are distinctly larger than ♂♂, averaging about 7 cm higher at the withers, and on average 8% larger body mass. Females have four inguinal nipples. Bodmer & Rabb (1992) and Lindsey *et al.* (1999) have provided a detailed description of the Okapi, including variability in coat patterns found in a sample of animals from the central Ituri that were brought into captivity at Epulu.

The skull is elongated, the long braincase in line with the facial part of the skull, and not flexed. There is a large parietal region, and short diastema. The lacrimal fossae are large. The large auditory bullae, and the large frontal and palatine sinuses are unique to the Okapi and separates it from the Giraffe (Colbert 1938, Bodmer & Rabb 1992). The horns measure 6–15 cm in length in ♂♂, but are absent (or rarely present in very reduced form) in ♀♀. These horns ossify and fuse with the frontal bones supraorbitally as the animal matures (Churcher 1990); horn development in ♂♂ begins around one year of age (Bodmer & Rabb 1992). There is no median ossicone. The cheekteeth are low crowned; the deciduous and permanent canines are incisor-like, while the incisors form a semi-circle at the end of the jaw. Skull development and tooth eruption are discussed by Jaspers & de Vree (1978).

Geographic Variation There are no currently recognized subspecies. Okapi populations occurring west and south of the Congo R. are reported to be overall darker than those to the east and north (I. Liengola pers. comm.). While the Congo R. must be a major biogeographical barrier for a species not known to swim, the genetic relationships between populations on either side of this river await investigation.

Lateral, palatal and dorsal views of skull of Okapi *Okapia johnstoni*.

Okapi *Okapia johnstoni* skeleton.

Similar Species In local parlance, might be mistaken for Bongo *Tragelaphus eurycerus* (due to striping), and sometimes even referred to as a zebra (this harkening back to the original misconception of the identity of the species). In the forest, the dung and tracks are distinct from other ungulates, with Okapi tracks being more rounded than Bongo, and smaller than African Buffalo *Syncerus caffer*.

Distribution Endemic to Africa. The Okapi is confined to the forests of DR Congo, occurring between about 500 m and 1500 m elevation over a fairly large range, on both sides of the Congo R. The Okapi ranged occasionally into the adjoining Semliki forest of extreme W Uganda in the recent past (Kingdon 1979). In the forests east and north of the Congo R., the Okapi is known from about latitude 1°S, in a broad arc north through the Maiko and Ituri Forests, then west through the Rubi, Tele and Ebola river basins (irregularly, to the Ubangui R.). The Okapi is also present in central DR Congo, west and south of the Congo R. in the forests of the upper Tshuapa and Sankuru Districts, from the west bank of the Lomami between 1 and 2°S latitude, west to the upper Lomela and Tshuapa basins (confirmed by I. Liengola pers. comm.). The forest–savanna transition defines the eastern and northern limits of the Okapi's range. In contrast, the southern limits east of the Congo R., and the western and southern limits of the species in C DR Congo, are poorly defined. In the west, the species does not appear to occur very far to the west of 24°E. The southern and western limits are not associated with any apparent biogeographical barriers, such as changes in vegetation type and elevation or occurrence of major river barriers (neither do overall forest composition and forest structure change over most of the apparent range boundaries).

The Okapi appears to be absent from large areas of closed-canopy forest in E and C DR Congo. Incidental reports of Okapi occurrence (mapped in Kingdon 1979) and rumours of Okapi presence persist in areas well beyond their currently known range. Okapis are secretive and shy, and their occurrence, especially at low densities, can easily go undetected.

The primary strongholds of the Okapi today are the Ituri/Aruwimi and adjacent Nepoko basin forests, and the forests of the upper Lindi, Maiko and Tshopo basins. The species is also well known in the Rubi-Tele region in Bas Uele. Up until the last two decades of the twentieth century, the Okapi's occurrence remained essentially the same as when it was discovered in the first decades of the century. However, since 1980, major expansions of human settlement

Okapia johnstoni

accompanied by deforestation and forest degradation, have eliminated important portions of their range, in particular in the southern and eastern Ituri Forest, where the species was at one time abundant. The type locality of the Okapi at Mundala has been overtaken by expanding settlement from the growing urban centre of Beni.

Habitat The Okapi is limited to closed-, high-canopy forests, occurring in a wide range of primary and older secondary forest types. It does not range out into gallery forests or into the forest islands on the savanna ecotone and it does not persist in the disturbed habitats surrounding larger forest settlements. Okapis will also forage in regenerating clearings abandoned by shifting cultivators when these are small (generally <1 ha), and when they occur within a habitat complex dominated by forest. Okapis use seasonally inundated areas when the substrate is still wet; however, they do not occur in truly inundated sites or extensive swamp forest. Okapis also do not frequent large areas of dense herbaceous Marantaceae and Zingiberaceae thicket. In the hilly areas of the northern Ituri Forest, where the species is common, Okapis seasonally move into rocky inselbergs during the wet seasons where selected forage plants, uncommon elsewhere, are in full leaf. Okapis, along with most of the other forest ungulates, visit mineral and clay excavations created and maintained by elephants, but they avoid the muddy wallows that also occur in these sites.

Radio-collared Okapis on the Egoro Study Area, in the Réserve de Faune à Okapi (RFO), north-west of Epulu, favoured areas of upland closed-canopy forest with a variably dense and diverse understorey of treelets and shrubs. These areas often had an overstorey canopy dominated by the fine-leaved *Cynometra alexandri*, and a relatively high proportion of deciduous trees (Hart & Hart 1989). This closed, but not heavy, canopy permits filtered light to reach the understorey, favouring the growth of the shade-dependent sub-canopy trees and shrubs that constitute the bulk of Okapi diet.

Tree fall gaps are selected foraging sites for Okapis during the early stages of regeneration (Hart & Hart 1989). Gaps are most heavily

exploited shortly after they are formed, following the emergence of seedlings and the flush of regenerating foliage on plants surviving the tree fall. By the time the gaps are 12–18 months old, most are filled in with vegetation that is either out of reach for Okapis, or not palatable to them, and they no longer use these areas preferentially.

The overall habitat preferences of Okapis suggest a species that evolved in relatively dry, though not strongly seasonal evergreen forest environments. Such a forest type is not widely represented in Africa today, though may have been more widespread during the later Miocene, and through periods of glaciation in the northern hemisphere, as the continent became drier. This suggests that across much of their range today, Okapis could be occupying sub-optimal environments. The remaining strongholds of the species in NE DR Congo may, in fact, be relictual remnants of habitats that by and large have disappeared as the continent returned to warmer and wetter climates in the later Quaternary through to the present.

Abundance Okapi density in the mixed *Cynometera* forests of the Edozo Study Area averaged 0.53 animals/km² (Hart, J. A. & Hart, T. B. 1988). Over a five-year period, 20–35 animals, of which about one-third had radio collars, were estimated to use the 50 km² Edozo Study area on an annual basis. Line-transect counts of Okapi droppings in this area of known Okapi density were used to calibrate counts conducted more widely over the RFO. Okapi density in the RFO varied from 0.1 to 1.2 animals/km², with an average density of 0.45 animals/km² and a total estimated population of about 6500 Okapis in the 13,700 km² reserve (Hart & Hall 1996). Somewhat lower densities were recorded in the northern and central Maiko N. P., where some 4000 Okapis were estimated to occur (Hart & Hall 1996). Okapis decreased south of the Maiko–Oso divide, and have not been found south of the Oso R. Okapis were found at lower densities and more patchy occurrence in the Rubi Tele and (Ebola R.) forests. Extrapolating Okapi density estimates from surveyed areas, in conjunction with available information on hunting, human settlement and habitat suitability within the Okapi's range, yields a global estimate of 35,000–50,000 animals over an estimated range of about 200,000 km².

Adaptations The Okapi is the only living large African ungulate that depends primarily on foliage from the forest sub-canopy for its diet (Hart 2001, Cerling *et al.* 2004). While this provides the Okapi with

a unique niche, their trophic specialization is nevertheless constrained by the overall low productivity of the forest understorey relative to more open environments. Palatable foliage is uncommon and dispersed in the forest understorey. Leaf flush is infrequent and most understorey foliage consists of mature, chemically protected leaves. The limited availability of suitable forage is all the more significant for the Okapi given the animal's large body size and large daily intake needs, averaging from 3.6 to 5.6 kg dry matter/day in captives (Bodmer & Rabb 1992, Hummel *et al.* 2006). These constraints have affected their diet and foraging ecology, as well as their social system and use of space. Yet, in spite of these constraints, young Okapis have one of the fastest growth rates known among artiodactyls, suggesting that heavy predation of young might have selected for rapid growth, presumably fuelled by exceptionally nutritious milk.

Okapis exhibit a number of morphological features that are associated with its specialization as a highly selective folivore. These include fine cusped, low-crowned teeth, adapted for shearing and cutting soft foliage; an elongated, tubular muzzle; and a long, muscular and mobile tongue (which can extend some 25 cm beyond the snout) with which the Okapi can dexterously select and strip foliage from even the finest twigs. Okapis produce copious saliva (and have large salivary glands, resembling those of the Giraffe; Burne 1917), which likely helps them control the protein and carbohydrate binding effects of tannins and other toxins in their foods. Okapis also have a large caecum and colon that assist in microbial digestion (Derscheid & Neuville 1924). They also have a very fast rate of food passage, which allows for lower cell wall digestion than for other ruminants (Prins & Domhof 1984). Characteristics of the morphology of the digestive tract are described elsewhere (e.g. Clauss *et al.* 2002) as are other aspects of digestion and food retention time (e.g. Hummel & Kolter 2003).

The heart of the Okapi is similar to other ruminants (with a weight of approximately 1.85 kg in an adult), and while the jugular vein resembles that of the Giraffe, the axillary and brachial veins are much less complex in the Okapi (see Bodmer & Rabb 1992, and references therein).

Foraging and Food Although Okapis feed preferentially in tree-fall gaps, these represent relatively small and ephemeral food patches. Their staple forage is the mature (though not senescent) foliage of understorey treelets, shrubs and lianas. Diets are dominated by foliage of woody, dicotyledonous species, with monocotyledonous species and herbaceous forbs (including ferns) infrequently eaten. Okapi diets are highly diverse. Foraging animals frequently move between different plant species as they feed, and feed selectively even within an individual plant, smelling and touching foliage with their muzzle and lips before wrapping their tongue around the twig or small branches and stripping the leaves. Dominant plant families in Okapi diets in the Ituri Forest include Acanthaceae, Ebenaceae, Euphorbiaceae, Flacourtiaceae, Loganiaceae, Rubiaceae and Violaceae. Subdominant families include Apocynaceae, Cecropiaceae, Moraceae, Meliaceae, Myrtaceae, Pandaceae, Sapindaceae, Ulmaceae and Vitaceae. Light-dependent saplings of a number of species that regenerate only in treefall gaps are among preferred forage, including *Alstonia boonei*, *Ricinodendron heudelotii*, *Musanga cecropioides*, *Macaranga* spp., *Tremma guineensis* and *Staudtia* spp. (Gijzen 1959, Hart & Hart 1989).

Okapis have a particular preference for foliage of canopy trees that have been broken, but not killed, and subsequently coppice, usually in treefall gaps. These include species that the Okapi will not use at

Okapi *Okapia johnstoni*.

all when they occur as saplings in the understorey. This suggests that many plants may be investing in ungulate-specific feeding deterrents while they occur in the understorey, but that these defences are relaxed as the plant grows into the canopy.

Social and Reproductive Behaviour Okapis are generally solitary, and spend a high proportion of their time standing still, concealed in the forest understorey. Adult ♂♂ on the Edozo Study Area have annual home-ranges of 10 to nearly 17 km² that overlap with those of other ♂♂. Adult ♀♀, in contrast, occupy exclusive home-ranges that vary from 4 to 7 km² (Hart & Hart 1989). Males have highly irregular movements, sometimes occupying relatively small areas of their home-range for days to one week or more, and then abruptly moving long distances to another area. Adult ♀♀ move steadily around their home-ranges, which they only infrequently leave. Home-ranges of breeding ♀♀ have a higher representation of favoured understorey food plants than occurs overall in the forest understorey on average. These plants show signs of heavy browsing during periods when ♀♀ are lactating or are accompanied by their young.

Okapis mark tree trunks by rubbing their neck, leaving on occasion a brownish exudate. Male Okapis mark understorey vegetation by urinating on low shrubs and then walking over or through the foliage. Okapi urine has a strong and distinctive odour and some marking sites are detectable even to the human nose. Both sexes stomp, usually with their front feet, and often after arriving in a new location following directed movement. While this may have infrasound properties, it is also likely that stamping is accompanied by the expulsion of secretion from the highly developed pedal glands and may therefore combine an auditory and olfactory signal. Captive animals may use common defecation sites as marking behaviour (Bodmer & Rabb 1992).

Combat in Okapis has not been observed directly; however, one ♂ caught in the wild had gashes on its side that may have come from the horns of another ♂. Two collared ♂♂, found dead in the same open pit, appeared from the trampled vegetation on the site to have physically confronted each other and pushed each other into the hole.

Play has been observed in all ages and both sexes, though most frequently in young animals. In a play behaviour unique to Okapis termed the 'pooky', the animal stands or spins, with head low and extended, accompanied by vigorous tail wagging (Bodmer & Rabb 1985). In the wild, young Okapis have been seen to greet their mother by gambolling and capering around them (J. A. Hart & T. Hart pers. obs.).

Breeding in free-ranging Okapis takes place on female home-ranges. More than one ♂ may visit receptive ♀♀ over successive days. Both sexes exhibit flehmen behaviour. In free-ranging Okapis, ♂♂ approach the larger receptive ♀♀ cautiously with lowered head, uttering low chuffing calls. Females respond by assuming submissive postures. Mating is rapid, and ♂♂ use a front leg forward kick. In captivity, where ♂♂ and ♀♀ have more continuous contact, ♂♂ can become aggressive with ♀♀. In the wild, male Okapis may spend several hours in the vicinity of receptive ♀♀ over a period of several days.

Females usually stand throughout labour, and eat the afterbirth. From observations in captivity, there is extensive grooming and close contact between mother and calf immediately following birth (Rabb 1978). Infants are precocial and initiate first nursing bouts on average within an hour of birth (Rabb 1978). Infants are then left in a concealed nest, and are only occasionally visited by the mother during the first weeks after birth. Mothers announce their arrival near the young with

a low chuffing sound and young may move quickly to the approaching mother while she is some distance off. Infrasonic calls have been recorded in captive Okapis and these may be used to communicate between mother and young (Lindsey *et al.* 1999). As they grow, young gradually increase their movements, but will still be visited by the mother. Subadult Okapis shifted their home-ranges gradually over time, but some radio-collared subadults, including both ♂♂ and ♀♀, also dispersed from stable, and presumably natal, home-ranges with long movements to new areas (J. A. Hart & T. Hart pers. obs.).

Okapis have only rudimentary vocal chords, with the result that their vocal repertoire is limited. The three best-documented sounds are the chuff, moan and bleat. Chuffs are contact calls used by both sexes and all ages; bleats are uttered by young infants, usually under stress; moaning is elicited by ♂♂ during courtship (Bodmer & Rabb 1985, 1992).

Reproduction and Population Structure Okapis reach adult size at three years, but may breed earlier in captivity (Bodmer & Rabb 1992). Oestrous cycles of captive females are not seasonal and average 14–15 days (Schwarzenberger *et al.* 1993). Breeding is aseasonal. Gestation periods ranging from 414 to 493 days have been recorded, with an average of 440 days in captives (Bodmer & Rabb 1992, and references therein); Schwarzenberger *et al.* (1993) used faecal pregnanediol measurements to determine gestation length in three animals at 423, 424 and 431 days. There is a rapid postpartum oestrus, and captive ♀♀ have recycled and become pregnant within a month or two of birth (Gijzen & De Smet 1974). Twinning is rare (Pearson *et al.* 1978). New-born Okapis range in body weight from 14.6 to 32 kg, and have among the most rapid growth rates of any ungulate species of their body size, tripling birth-weights in the first 50 days (Bodmer & Rabb 1985); male calves have higher percentage increases to begin, but by week 8 their increases are equal to ♀♀ and thereafter their increases are lower than female calves (Boylan *et al.* 2004). The milk of the mother has a very high concentration of protein (one-third higher than cows' milk) and a low fat content (Gregory *et al.* 1965; and see Petric 2004b). Infants in captivity take solid food by the third week, and begin ruminating at around six weeks. Weaning takes place at about six months, although young may continue to suckle for longer. Lindsey *et al.* (1999) summarize extensive observations on reproduction and breeding in captive Okapis. The longevity record for a captive Okapi is 33 years 6 months and 10 days (Galbusera & Leus 2004), and one ♀ reproduced successfully at 26 years of age (Gijzen & De Smet 1974).

Predators, Parasites and Diseases Leopards *Panthera pardus* are the major predator of Okapis: nearly 18% of radio-collared Okapis were killed by Leopards over the five-year Edozo study, with younger animals and adult ♂♂ the most frequent prey. One young Okapi was killed by snake-bite. Over 30 species of parasitic roundworms, nematodes and helminths have been recorded in Okapis. Infestations of the nematode *Monodontella giraffea*, affecting the bile ducts and liver, have been associated with morbidity and mortality of animals brought into captivity in the Ituri Forest. These parasites have been implicated in the death of a number of captives; however, their effect on health, reproduction and predator avoidance in free-ranging animals is not known. Captive animals have shown susceptibility to various bacterial infections, and bacterial and fungal diseases (Bodmer & Rabb 1992, and references therein).

Conservation IUCN Category: Near Threatened. CITES: Not Listed.

The Okapi is a totally protected species under Congolese law and the species is a national symbol, appearing on the insignia of the Congolese National Parks Institute, ICCN. There are two protected areas within the Okapi's principal range, namely Maiko N. P. and the Réserve de Faune à Okapi, one of DR Congo's five UNESCO World Heritage sites. An additional protected area, the Rubi-Tele Hunting Reserve, also occurs in the Okapi's range, although the level of protection is lower. A small population of Okapis still occurs in the northern sector of Virunga N. P., in the Congolese portion of the Semliki Forest (M. Languy pers. comm.).

Okapis are vulnerable to hunting, and decline rapidly in areas where there is persistent use of cable snares. ICCN staff have occasionally found skins among contraband confiscated from poachers. Okapi skins were reportedly readily available on the illegal market during the civil war of 1998–2003. The Mbuti hunter-gatherers in the Ituri Forest hold Okapis in high esteem. While this has not prevented them from killing Okapis, it has elevated this to a special event that requires post-hunt purification. In at least one directly observed case, these taboos actually led a hunter to allow an Okapi to escape unharmed (J. A. Hart pers. obs.)

The greatest risk to the survival of Okapis is the opening of the forest to settlement and logging. Approximately one-third of the Okapi's known area of occupancy is likely to be at risk by major incursions during the first quarter of this century. Areas at high risk include the south-eastern Ituri Forest, the Kisangani area, Rubi-Tele and the western limits of the species' range in the Ebola R. basin. Strengthening protection of the Réserve de Faune à Okapi and Maiko N. P., both of which contain significant Okapi populations, is the single most important means to ensure long-term survival of Okapi. Okapis can coexist with small-scale, low level human occupation of the

forest, but they disappear in areas of active settlement or disturbance.

Okapis have been captured and brought into captivity at Epulu, headquarters for the RFO, since the early 1950s, where a captive population has been maintained in large enclosures for nearly fifty years. These animals have been the source of exports to the world's zoos and also offer a unique opportunity to view Okapis under conditions that approach their natural setting. In June 2012, armed militia opened fire on the RFO headquarters, killing six people and 14 Okapis.

Superfamily CERVOIDEA

DEER

Cervoidea Goldfuss, 1820. Handb. Zool. 2: xx, 374.

Cervoidea represent one of just three 'true ruminant' superfamilies in the infraorder Pecora, the others being Giraffoidea and Bovoidea. According to the molecular clocks devised by Hassanin *et al.* (2012), their common ancestor diverged from traguloids (ancestral chevrotains) in the early Eocene (about 51 mya), a date that is substantially at odds with the fossil record in which the earliest pecorans (the extinct gelocids) only appear in the Asian Oligocene. This ancestral pecoran stock evolved in Eurasia and the Cervoidea only began to differentiate from giraffes in the Oligocene. Molecular data put the date of that divergence at about 23.4 mya and suggests that they then diverged from a common bovoid stock at about 22.4 mya (Hassanin *et al.* 2012; fossils suggest that the earliest modern type of pecoran emerged about 23 mya (Cote 2010).

Both cervoids and bovovoids are, therefore, the most recently evolved of ungulate superfamilies. The former is widely distributed over Eurasia and the Americas but most diverse in South-East Asia and South America, whereas bovovoids, while abundant and diverse in

Eurasia, much less so in North America, are most highly differentiated in Africa.

While the basic features of rumination were clearly evolved in their common ancestor, further refinements, particularly those concerned with digesting coarse grasses, are essentially late adaptations that run parallel to those of bovovoids, both having continued to diverge and adapt to different diets (Hofmann 1989).

Although climatic boundaries between the two superfamilies are blurred in both contemporary species and in the fossil record, the overall pattern suggests that they originally aligned themselves along the extremities of a geographic and temperature gradient. Eurasian cervoids made an early accommodation to the seasonality and cold of upper latitudes, while various degrees of resistance to heat may have been a major advance for early bovovoids. This may well have inhibited cervoids from invading Africa, particularly if there was any sort of drought belt separating the two continental masses (Thomas 1979b). It is interesting that cervids have been very successful in tropical and

sub-tropical South America within the last 2 mya, but it is surely relevant that this radiation took place in the total absence of bovid competition (C. Janis pers. comm.).

Considering their long common ancestry, it is not surprising that deer and bovids have much in common and are frequently confused with one another in common parlance. Deer have no significant history in Africa, yet, for historical reasons, some African antelopes owe their earliest European names to cervid prototypes, such as ‘eland’ and various ‘bucks’ and ‘boks’. Although deer resemble antelopes very closely in body proportions and ecological niches, their regional origins, and sometimes their continental ones, differ. Likewise, although deer have preorbital, metatarsal, caudal and interdigital scent glands, it is unlikely that these are exactly homologous with similar glands in bovids. The most primitive species have sharp blade-like sabres, like the chevrotains’ upper canines. More advanced forms have tusks and antlers, which serve as defensive

weapons against wounding by canine teeth. In other species, antlers have acquired elaborate branched structures and secondary uses in head-to-head clashes and ‘wrestling’. Unlike the fixed horns of bovids, antlers are shed each year (their fast annual growth has physiological resemblances to forms of wound-healing processes, which suggests that antlers may have evolved from a type of scar-tissue). Antlers first appear in the fossil record in the early Miocene of Eurasia (Gentry *et al.* 1999).

Cervoidea currently includes two families: Moschidae (musk deer), which are entirely extralimital, and the Cervidae (true deer), of which only a single species occurs in Africa. Inclusion of Moschidae in Cervoidea is equivocal, and the family may be more closely related to Bovidae (see Hassanin & Douzery 2003).

Jonathan Kingdon

Family CERVIDAE
DEER

Cervidae Goldfuss, 1820. Handb. Zool. 2: xx, 374.

| | | |
|--------------------|----------|--------|
| Cervus (1 species) | Red Deer | p. 117 |
|--------------------|----------|--------|

The family Cervidae contains the deer. The most recent classification of the family (Grubb 2005) recognizes 51 species, divided among three subfamilies: Capreolinae, Cervinae and Hydropotinae (although the status of the latter is uncertain). The family is widespread throughout the New World and the Palaearctic, although they have also been widely introduced in places as far flung as islands in the Caribbean and Australia and New Zealand (Whitehead 1993, Geist 1999).

Characteristic of adult male cervids are the antlers: only in one (boreal Holarctic) genus, *Rangifer*, are antlers constantly developed in ♀♀. Antlers are absent only in the Hydropotinae, a monotypic subfamily represented by the Chinese Water Deer *Hydropotes inermis*, from China and Korea. Antlers grow in spring as cranial apophyses, covered by highly vascularized skin called velvet; they grow rapidly, usually with a branched structure. In early autumn they reach full growth and the velvet dries up and is shed in patches. The antlers, now solid bone, are used for male–male combat and male–female display, and after the rut are shed. The antlers regrow each year.

Cervids have a battery of premolar and molar teeth (the dental formula is $I^{0/3} C^{0-1/1} P^{3/3} M^{3/3} = 32-34$) with enamel selenes; incisors and canines form a continuous cutting series in the lower jaw, but in the upper jaw the incisors are replaced by a toothless pad, and the canines, usually confined to ♂♂, are short and pointed (though well

developed in some genera, such as *Muntiacus*). The jaws are powerfully developed, with a broad angle at the back where the chewing muscles are attached. The braincase is wide, the orbits (eye-sockets) are tubular and face to the side, and are entirely ringed by bone; the visual fields do not overlap, instead cervids have all-round vision.

In Africa there is only a single indigenous species of deer, the Red (Barbary) Deer *Cervus elaphus*. Fallow Deer *Dama dama* were introduced to Groote Schuur farm in South Africa in 1897, although they had been kept in the grounds at Newlands House in Cape Town as early as 1869. Subsequently, they were widely introduced throughout the country and still are widespread; introduced Red Deer have done less well. Other species released on ranches include Chital *Axis axis*, Hog Deer *Axis porcinus* and Sambar *Rusa unicolor*. Records of Fallow Deer from NE Algeria are likely due to confusion with Red Deer (Kowalski & Rzebik-Kowalska 1991). On the other hand, Brentjes (1969) found archaeological evidence to suggest that Fallow Deer in Ancient Egypt and Ethiopia were not imported, but may have survived in Ethiopia until relatively recently. By and large, the introductions of non-native deer to Africa have not fared well. During the Pleistocene the shores of the Mediterranean and its islands were home to several species of megacerines, the lineage of giant deer. Of these only the Fallow Deer survived into the present.

Colin Groves

Subfamily CERVINAE – Old World Deer

Cervinae Goldfuss, 1820. Handb. Zool. 2: xx, 374.

Subfamily Cervinae (the Old World deer) includes two tribes: Cervini, comprising the genera *Axis*, *Cervus*, *Elaphurus*, *Przewalskium*, *Rucervus*, and *Rusa*; and Muntiacini (*Elaphodus* and *Muntiacus*) (Grubb

2005). Only the former is represented in Africa, and then by a single species, the Red Deer *Cervus elaphus*.

GENUS *Cervus*

Red Deer

Cervus Linneus, 1758. Syst. Nat., 10th edn, 1: 66.

In Africa the genus *Cervus* is represented by a single species, the Red (or Barbary Red) Deer *Cervus elaphus*, which is known to have occurred since the Pleistocene (Geraards 1982, Kowalski & Rzebik-Kowalska 1991, Aulagnier 1992, Laquay 1992), but is now represented by vestigial populations in Algeria and Tunisia. In spite of Red Deer being known from North Africa since the Pleistocene, it is possible that extant Red Deer in North Africa are the product of, or have been genetically influenced by, very early reintroductions from Europe (Davis 1984, Corbet 1978, Dolan 1988, Geist 1999). Whatever the genetic status of North African deer, it is clear that *Cervus* has always been a very marginal genus in Africa. Species belonging to this genus are widespread throughout Eurasia and North America and their ancestral stock probably evolved in Central Asia (Brooke 1878, Groves & Grubb 1987, Janis & Scott 1987, Ludt *et al.* 2004).

There is reason to suspect that Red Deer were repeatedly transplanted by human hand around the Mediterranean basin beginning as early as 8000 BP (Davis 1984). This habit continues into the present as exemplified by the 1952 introduction of Red Deer from Spain along

the coast of N Morocco (Ksar-es-Seghir), where Red Deer were probably found in early historic time. Sika Deer *Cervus nippon* were also introduced there between 1951 and 1953. The Spanish Red Deer *Cervus elaphus hispanicus* released in 1952 have since become established in two small populations (south of Tétouan); the introduced Sika Deer apparently failed to establish themselves.

There are reports of Red Deer having been introduced in 1954 to the island of Bioko (formerly Fernando Poo) off the coast of Cameroon in the Gulf of Guinea (Haltenorth & Diller 1980, Whitehead 1993), but there is no mention at all of this in the works of Basilio (1962) or Eisentraut (1973) and, since several authorities who have spent many years working on the island have been unable to confirm these reports (J. Oates, T. Butynski, J. Juste and J. Perez pers. comm.), it must be regarded as doubtful that Red Deer were ever introduced on Bioko. The origin of the records could stem from confusion from the use of the term 'red deer' for red duikers *Cephalophus* spp. in various dialects (and even in Spanish 'vernados') in that part of Africa.

Valerius Geist

Cervus elaphus RED DEER (BARBARY RED DEER)

Fr. Cerfe de Berberie; Ger. Berberhirsch

Cervus elaphus Linnaeus, 1758. Syst. Nat., 10th edn, 1: 67. S Sweden.Barbary Red Deer *Cervus elaphus barbarus*.

Taxonomy The subspecies of Red Deer that occurs in North Africa is *C. e. barbarus*, which has its type locality in Tunis, near the Algerian/Tunisian border. The information presented in this profile relates specifically to this Red Deer subspecies, which, irrespective of its aboriginal origin, looks like a West-European Red Deer and as such may have been reintroduced into North Africa. Therefore, its taxonomy cannot be judged independently of that of Red Deer from other locations around the shores of the Mediterranean. Great faunal shuffles began here in early Neolithic times, when indigenous faunas of dwarfed island deer, elephants and hippos were abruptly replaced by sheep, goats, Fallow Deer, Red Deer and pigs (Davis 1984), indicating considerable skills at navigation and seamanship in early Neolithic cultures. This is supported by the external appearance of Red Deer from Italy, Corsica, Sardinia and North Africa, which are all West European in their coat characteristics as well as in the rutting roars of the stags. The Red Deer of S Spain (*C. e. hispanicus*) are distinctly different in coat characters from West-European Red Deer and differ somewhat in their rutting calls (Geist 1999).

On islands such as Corsica and Sardinia, Red Deer evolved island dwarf characteristics, such as small body size and short legs, while those exposed to mainland conditions remained normal Red Deer. Numerous scholars have remarked on the similarity of Red Deer from north-west Africa to animals from the islands of Sardinia and Corsica, and Flerov (1952) considered all Mediterranean Red Deer one subspecies (*C. e. corsicanus*); Corbet (1978) also included *C. e.*

barbarus as a synonym of *C. e. corsicanus* (and see Pitra *et al.* 2004), and an affinity with Sardinian Red Deer is borne out by molecular studies (Ludt *et al.* 2004). The current Red Deer of North Africa may be as much an artefact of human culture as are other European Red Deer, but one with minor genetic adaptations and phenotypic adjustments to Mediterranean climatic and biotic conditions (Geist 1999). Synonyms: there are numerous synonyms (see Grubb 2005 for review), but only *barbarus* pertains to African forms. Chromosome number: $2n = 68$.

Description Small-bodied form of Red Deer with a yellowish rump and a coat very similar to the West-European Red Deer *C. e. elaphus*. A character often mentioned is the light spots running in longitudinal lines along the dark mid-dorsal line. The spots are fainter in the dark brown winter coat than in the reddish-yellow summer coat. The conspicuousness of the light spots thus appears to be a function of the length and density of the winter coat, the spots being more conspicuous in struggling populations in warm climates, growing a thin winter coat for reasons of climate and resource shortages. The coat is in all other respects the same as that of the West-European Red Deer, except for hair density. The neck mane in ♂♂ is sparse in the winter coat, and is absent during the mating season as the stags rut essentially in their summer coat. There is much individual variation in coat characteristics. In captivity, these Red Deer reach sizes and appearance typical of northern West-European Red Deer (Meyer 1972, Kacem 1986, Dolan 1988, Whitehead 1993). As with European Red Deer, they have preorbital, metatarsal, caudal and interdigital (hindlegs only) scent glands. Females have two pairs of nipples.

The antlers are small and simple in structure as expected of a small-bodied deer. The bez tine is usually absent; the brow tines and beams tend to be short; occasionally antlers terminate in cup-shaped crowns. Antlers are shed at the beginning of winter, and start growing in Mar.

Geographic Variation None recorded in the species' North African range (and see Taxonomy).

Similar Species In its North African range this species is unlikely to be confused with any other species.

Distribution Red Deer were very popular in North Africa in early historic times as revealed by mosaics and abundant archaeological remains in ancient Carthage and other localities in Algiers and Tunisia. A Pleistocene fossil find in Algiers appears to be that of a Red Deer (Kacem 1986) and the species has been recorded from the late Pleistocene and early Holocene of Morocco (Geraards 1982, Aulagnier 1992, Laquay 1992). They were much more widespread and abundant in Neolithic and early historic times than they are today (Dolan 1988), occurring throughout north-western Africa from Tunisia west to Morocco, although they may have disappeared from Morocco already in Roman times.

In recent times Red Deer have been increasingly confined with remnant populations occurring in NE Algeria and NW Tunisia (Kacem 1986, Dolan 1988, De Smet 1989, Kowalski & Rzebik-Kowalska 1991, Whitehead 1993).

Lateral, palatal and dorsal views of skull of Red Deer *Cervus elaphus*.

Cervus elaphus

Habitat The Red Deer in North Africa currently occupies dense sub-humid, evergreen, montane scrub forests of oak and pine up to 1200 m in altitude.

Abundance There is very little information available on the status and abundance of this species. Salez (1959a, b) discussed their status and distribution in 1953, proposing a total population of some 300–400 individuals. Subsequently, Kock & Schomber (1961) estimated a population size of 200 animals in 1959. In Algeria, the total population in the mid-1970s was reported to be 400–600 (Halis 1975), and by the late 1980s reached an estimated 2000 animals (Dolan 1988, De Smet 1989). However, this population is known to have since declined (K. De Smet pers. comm.), although there are no recent population estimates. The population on the

Tunisian side apparently suffered a dramatic bottleneck with only seven specimens reported to remain in 1962 (Dolan 1988). Genetic data reflect this bottleneck event, but also show that genetic variability of Tunisian Red Deer has not been severely reduced, likely due to augmentation from animals immigrating from Algeria (Hajji *et al.* 2007). The population subsequently increased following conservation interventions, and was estimated at about 800 animals in 2006 (Oumani, in Hajji *et al.* 2007), much lower than the figure of 2000 mentioned by Dolan (1988).

Adaptations The short antlers and antler tines suggest significant food restrictions in summer, particularly during early antler growth, as well as difficult overwintering conditions. The small body size suggests disruptions during the periods of intense postnatal body growth, perhaps indicative of shortages of high-quality food during much of the year, punctuated by brief periods only of forage abundance. The sparse winter hair coat suggests adaptation to a warm climate, as well as resource shortages. Captive and expanding, low-density populations appear to be exempt from food shortages, and respond with body and antler growth comparable to individuals in European populations.

Foraging and Food Much of the food comes year-round from the forest's undergrowth of herbs and shrubs, such as browse and foliage as well as seasonal fruit and acorn crops. The acorn mast and fruit season are especially important as during this season the deer assume their best condition. However, this deer's close dependence on dense forest may be a consequence of the long prosecution suffered by this deer. It chooses cover for security and, consequently, lives off the forage available in cover. Its current food habits, focusing on foliage and browse, may also reflect competition with livestock in overgrazed landscapes. These deer may raid field crops at night (Haltenorth & Diller 1980).

Social and Reproductive Behaviour The few observations available suggest that the social and reproductive behaviour of the Barbary Red Deer is much the same as in European Red Deer, but more subdued and carried out in greater secrecy (Haltenorth & Diller 1980). It is likely that severe persecution in modern times has led to significant deviations in the ecology of this deer from that of earlier times, including changes in hiding behaviour, reduced vocalizations, and nocturnal activity patterns in order to evade detection by humans. Where this deer chooses to stay, what it feeds on and what it does appears to be severely affected by humans, an example of distress biology.

The rut in Aug and Sep is early, suggesting an adaptation to birthing early in spring (Apr to end Jun) to catch the spring growth of vegetation and minimize the effects of summer droughts. Whereas the rut is noisy and conspicuous in many parts of the range, it tends to be more silent in North Africa. An extended calving season is typical of deer from warm climates, a means of reducing predation risk for neonates by dispersing them in time. Calves remain hidden for 2–3 weeks before joining the mother.

Reproduction and Population Structure Sexually mature at 18 months. Gestation lasts 235 days, and a single young is born, which suckles for about seven months. Longevity is usually 12–15 years, but may be up to 20 (Haltenorth & Diller 1980).

Predators, Parasites and Diseases No specific information is currently available. However, since this deer retained the typical body proportions of continental Red Deer, and shows no signs of evolving shorter legs as do Red Deer on Corsica and Sardinia, it may be safely assumed that it evolved under significant predation from large predators. In the past, Barbary Red Deer overlapped in distribution with Lions *Panthera leo*, Leopards *P. pardus*, Cheetahs *Acinonyx jubatus* and Golden Jackals *Canis aureus*. Today stray feral dogs are a more likely danger (Haltenorth & Diller 1980). Where Red Deer overlap with livestock they may become infected with livestock diseases and parasites.

Conservation IUCN Category: Least Concern. CITES: Appendix III (Tunisia).

Protected under national legislation in Morocco, Algeria and Tunisia. Barbary Red Deer were near extinction in the 1960s, mainly as a result of overhunting and habitat degradation from forest fires. Following the Algerian war for independence, conservation measures were put in place. In Tunisia, hunting was banned in 1963, and a forest reserve of 16,000 ha was established to conserve these deer. In 1966, a 417 ha breeding enclosure was established with 17 individuals near El Feidja, from whence animals were reintroduced to other reserves, including at Ain-Baccouch in 1975 (100 ha) and Mehebes in 1978 (300 ha). Deer subsequently increased in numbers, both in Tunisia and in Algeria (Kacem 1986, Dolan 1988, Trense 1989). In Algeria, the species occurs in El Kala N. P. and Beni Salah Nature Reserve; there is currently a joint project between the Forests General Directorate (DGF) and Zeralda Game Centre (Centre Cynégétique de Zeralda) aiming to reintroduce Barbary Red Deer in Akfadou forested areas (Kabylie region) (F. Belbachir pers. comm.). There are two enclosures in Morocco with captive animals, but there have as yet not been any reintroductions (F. Cuzin pers. comm.).

Superfamily BOVOIDEA

BOVOIDS

Bovoidea Gray, 1821. London Med. Repos. 15: 308.

The Pecora comprise three superfamilies of ruminating herbivores: Cervioidea (deer), Giraffoidea (Giraffe and Okapi) and Bovoidea (bovoids) and, in each case, the living forms of each of these superfamilies

do not differ between family and superfamily. Consequently, a summary of the characteristics of bovoids can be found in the family profile and needs no repetition here.

Family BOVIDAE

BOVINES, ANTILOPINES

Bovidae Gray, 1821. London Med. Repos. 15: 308.

| | | |
|-------------------------------------|-------------|--------|
| Bovinae (2 genera, 10 species) | Bovines | p. 122 |
| Antilopinae (29 genera, 76 species) | Antilopines | p. 199 |

The family Bovidae contains the cattle, buffalo, sheep, goats and antelopes, and includes more species than any other extant family of large mammals. According to the most recent classifications, informed by recent molecular discoveries, they belong to the order Cetartiodactyla, which combines the artiodactyls, or even-toed hoofed mammals, with the whales, dolphins and porpoises. As ruminating animals they belong to the suborder Ruminantia and to the infraorder Pecora, which also embraces Cervidae, Giraffidae, the (now non-African) Antilocapridae (North American Pronghorn *Antilocapra americana*) and extralimital Moschidae (musk deer).

Bovids, like the closely related cervids, have a battery of premolar and molar teeth with enamel selenes; incisors and canines form a continuous cutting series in the lower jaw, but in the upper jaw the incisors are replaced by a toothless pad. The typical dental formula is $I^{0/3}, C^{0/1}, P^{3/3}, M^{3/3} = 32$, although some species, such as the Springbok *Antidorcas marsupialis* and some members of the Alcelaphini (*Connochaetes* spp. and *Hirola Beatragus hunteri*), have lost the second lower premolar; instances of supernumary teeth are reported in other species (e.g. Bushbuck *Tragelaphus scriptus*). The jaws are powerfully developed, with a broad angle at the back where the chewing muscles are attached. The braincase is wide, the orbits (eye-sockets) are tubular and face to the side, and are entirely ringed by bone; the visual fields do not overlap, instead bovids have all-round vision.

The one major difference between bovids and cervids is in the nature of the horns. Bovid horns are epiphyseal: the horn consists of a bony core covered by a keratinous sheath, and is unbranched and permanent (never shed). Horns are intrinsically conical, but are often either keeled longitudinally, ringed transversely or pulled into a spiral by differential growth rates in the horn sheath. Horns may be present in both sexes, or restricted to ♂♂. Minor differences are that the lacrimal duct almost always opens in one circular orifice inside the orbital rim (exception: some *Tragelaphus*, *Bos* and *Bubalus*, in which the orifice may be on the rim, and there may be two orifices), whereas in cervids there are always two, and they are on the rim itself; and that the gully along the mid-line of the fused metatarsi is open for its whole length, whereas in cervids it closes above the distal end of the shaft.

Bovids include both browsers and grazers, and live in all African environments from rainforest to desert. Outside Africa, they live in

Lesser Kudu *Tragelaphus imberbis* head.

Head of Oribi *Ourebia ourebi* exposing series of deeper components of masseter and temporal muscles and general features of bovid head (from Kingdon 1982).

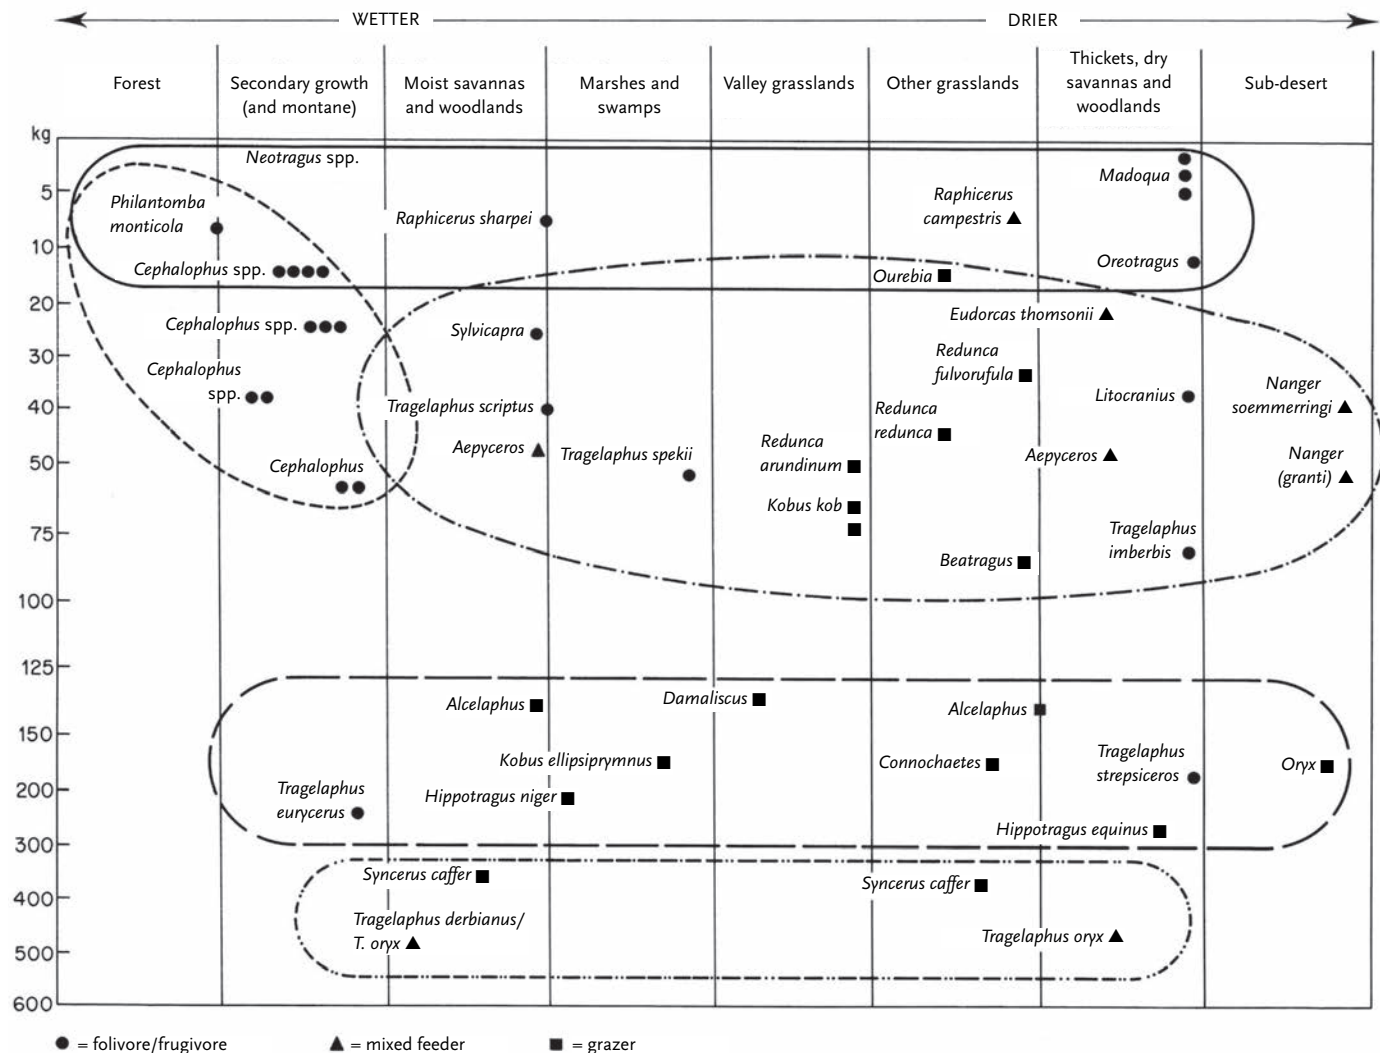

Europe, Asia and North America; however, it is in sub-Saharan Africa that their diversity is greatest, with 70 or more described species (and many more fossil forms), according to whether taxa in some allopatric species-groups are regarded as species or subspecies.

The phylogenetic relationships and taxonomy of this family have been the topic of much controversy (see, for example, Hernández Fernández & Vrba 2005 for review). The study of Gatesy *et al.* (1997), which combined morphological and molecular data, concluded that Bovidae is monophyletic, and this has been supported by subsequent molecular studies (Matthee *et al.* 2001, Hassanin & Douzery 2003, Hassanin *et al.* 2012). However, the classification of the family remains problematic, particularly with regards to recognition of tribes and subfamilies. In the current work, the primary subdivision is between subfamilies Bovinae and Antilopinae (contra Grubb 2005 who recognized eight subfamilies), the former mainly Eurasian, the latter predominantly African. Tribal relationships within the two subfamilies are far from settled as the molecular studies cited above attest. Other defining differences are discussed under the subfamilial and tribal profiles.

Colin Groves Bovid heads are transformed by the shape and orientation of their horns.

Table 6. Diversification of Bovidae.

Subfamily BOVINAE – African Buffalo, Spiral-horned Antelopes

Bovinae Gray, 1821. London Med. Repos. 15: 308.

| | | |
|--------------------------------|-------------------------|--------|
| Tribe Bovini | | |
| <i>Syncerus</i> (1 species) | African Buffalo | p. 124 |
| Tribe Tragelaphini | | |
| <i>Tragelaphus</i> (9 species) | Spiral-horned Antelopes | p. 138 |

Bovinae are distinguished from the antelopes (Antilopinae) by their generally larger sizes, an absence of facial or pedal glands, and smooth or keeled, rather than annulated horns.

African Buffalo *Syncerus caffer* head.

Until the advent of molecular science and its application to the phylogeny of bovids, there was great confusion as to the relationship between bovid groups that can now be separated into Bovinae and Antilopinae. The main source of this confusion was excessive reliance on the structure of teeth. Increasing graminivory in the more advanced Bovinae has wrought many dental convergences with equivalent large, grass-eating Antilopinae and these convergent resemblances in the breadth, depth and complex folding of enamel ridges (and in-fill with dentine cement) created great confusion in the past, leading to completely erroneous affiliations across the two groups of Bovidae, which were broken down into the so-called ‘Boodonts’, with a long, relatively narrow tooththrow, and ‘Aegodonts’, with hypsodont molars and a shortened premolar row (Schlosser 1904).

The primary divergence between Bovinae and Antilopinae probably had both an ecological and an intercontinental basis. Where food is locally unreliable animals must make periodic movements or become nomadic and selection for territorial behaviour and its associated anatomical structures is reduced or absent. However, animals can only use an unstable habitat if their off-season food is predictable and within reach and if they are adapted to the demands of an unstable existence. A bovid that has to move in search of food can acquire the advantages of more economic, efficient locomotion and a reduction of vulnerability to predators if it increases body size. This must be sustained by the certainty of adequate food and this, in turn, may involve fluctuating densities.

The combination of abundant but fluctuating food supplies might help explain the absence of facial and pedal glands, the rarity of

territorialism, and the trend towards hierarchy and large size. Most Bovinae are mobile and tend to form hierarchies in which ♂♂ generally avoid each other. Hierarchy encourages sexual selection in favour of larger ♂♂. Females are commonly hornless (or less heavily horned than ♂♂), but the development or suppression of horns in ♀♀ is neither primitive nor advanced. Rather, both conditions involve different mechanisms or strategies for getting at resources. Horned ♀♀ tend to resemble ♂♂ in establishing same-sex hierarchies and they are more active in defending their young.

There are three main groups within the Bovinae. In the species-level super-tree of Hernández Fernández & Vrba (2005), the most primitive of these is the Boselaphini (named after the Indian Nilghai *Boselaphus*), which separated around 20.5 mya. The tragelaphine or spiral horned antelopes, Tragelaphini, evolved in Africa from an Asian stock that resembled boselaphines (Gentry 1978). Their divergence took place about 18.3 mya (Hassanin *et al.* 2012), at which time there was a known connection between Eurasia and Africa (commonly called the Proboscidean event). Grubb (2001a) additionally proposed Pseudorygini as a new tribe within the subfamily Bovinae for the recently discovered Saola *Pseudoryx nghetinhensis*, but later (Grubb 2005) included Saola in Bovini.

Tribe BOVINI

African Buffalo

Bovini Gray, 1821. London Med. Repos. 15: 308.

The tribe Bovini includes at least four extant genera, with only a single living representative in Africa, the African Buffalo *Syncerus caffer*. Extraliminally, the tribe includes: *Bison* (two species), *Bos* (five species), *Pseudoryx* (one species), and *Bubalus* (four species) (Grubb 2005).

Recent molecular studies have broadly agreed with much older classifications in associating Bovini with the tribes Boselaphini (which includes the Nilgai *Boselaphus tragocamelus* and Four-horned Antelope *Tetracerus quadricornis*), which are also Asian, and Tragelaphini, the spiral-horned bovines, which are African, but derive from an Asian immigrant stock (Matthee & Robinson 1999a, Hassanin & Douzery 2003, Hassanin *et al.* 2012). The African Buffalo has been estimated to have separated from its closest relatives, the Asian Buffalo, *Bubalus* spp. between about 7.3 and 5.1 mya (Van Hooft *et al.* 2002), a period in which other exchanges between Eurasia and Africa took place.

Members of the tribe are large and heavy in build, and typified by low, wide skulls with a short face and smooth horns, present in both sexes, which tend to splay out sideways from the skull. Internal sinuses have developed at the base of the horn cores. Species tend to be plainly coloured, and there are no compound odoriferous glands. Females have two pairs of nipples.

Despite the still relatively widespread occurrence of the African Buffalo on the African continent, it is being replaced at a steady pace by the commonest bovin in Africa, the domestic cow *Bos taurus*, which is the descendant of the Aurochs *Bos primigenius*, once widespread in Europe, western Asia and North Africa. Water Buffalo *Bubalus bubalis* also have been introduced in North Africa in Egypt,

African Buffalo *Syncerus caffer*.

Libya and Tunisia, where African Buffalo are now absent, and a few are found in coastal agricultural lands of East Africa.

Jonathan Kingdon

GENUS *Syncerus*

African Buffalo

Syncerus Hodgson, 1847. J. Asiat. Soc. Bengal, ser. 2, 16: 709.

Syncerus is a monotypic genus represented by the African Buffalo *Syncerus caffer*, which is distributed throughout sub-Saharan Africa in habitats ranging from savanna to rainforest, in fact wherever permanent water is found. The most closely related living genus is *Bubalus* (Asian buffalo species), which also belongs to the tribe Bovini, and of which *Syncerus* has been considered a subgenus (Haltenorth 1963). According to genetic studies, the ancestors of these two genera diverged during the late Miocene between 7.3 and 5.1 mya (Van Hooft *et al.* 2002). This is a period with several speciation and migration pulses, initiated by widespread climatic changes (Hassanin & Douzery 1999). Other members of the tribe Bovini – the cattle (genus *Bos*) and bison (genus *Bison*) – appear to have diverged from African Buffalo between 14 and 10 mya (Pitra *et al.* 1997, Hassanin & Douzery 1999) at a time when such ancestral forms would certainly have been morphologically assignable to Boselaphini. The corollary is that Bovini are polyphyletic.

In recent history there was another African species of buffalo, the Giant Long-horned Buffalo *Pelorovis antiquus*, which disappeared from southern and East Africa about 12,000 years ago and from northern Africa about 4000 years ago (Klein 1994). The genus *Pelorovis* diverged from *Syncerus* around the same time as *Bubalus* (Gentry 1990). Fossil remains show that the horns were less dorsoventrally compressed and lacked the heavy bosses of the horns characteristic of the extant buffalo. Peters *et al.* (1994) argued that the postcranial anatomy of *antiquus* indicated that it was simply a long-horned morph of the extant *S. caffer*, and that therefore it should be called *S. c. antiquus*, but Klein (1994) demonstrated that *antiquus* is indeed distinct at species level as evidenced by its singular horns, some dental differences, and its geographic overlap with the latter species through most of the middle Quaternary. Klein envisaged the extinct buffalo as having been in drier and grassier habitats than *S. caffer*.

Taxonomy The classification of the African Buffalo has had a somewhat confusing past, detailed discussion of which is beyond the scope of the current work. There is much variation in pelage colour, body size, and shape and size of the horns, often but not always in a geographical context, and apparent intermediates between types are common. Ansell (1972) and Grubb (1972) summarized the earlier subspecific classifications of Lydekker (1913–1916), Christy (1929), Schouteden (1947), Blancou (1935, 1954), Malbrant (1935), Dalimier (1955) and Haltenorth (1963), and concluded that there seemed little doubt that all forms should be regarded as conspecific, including *nanus*, considered by many earlier authors as a distinct species (e.g. Christy 1929, Malbrant 1935, Schouteden 1947). More recently, three or four subspecies within *S. caffer* have been recognized, although the subspecies status of *S. c. aequinoctialis* has been unclear; an East African mountain form (*mathewsi*) has also been treated as distinct (e.g. Kingdon 1982, Grubb 2005).

The subspecies classification presented here is provisional, and is based on East (1999) and Grubb (2005). However, according to mitochondrial DNA data, African Buffalo from East and South Africa comprise a single clade, while populations from Cameroon, Gabon, Angola and, apparently, Namibia form another (Van Hooft *et al.* 2002). The latter study found that African Buffalo have high within-population mtDNA diversity, with little differentiation between populations. One possible explanation for these observations is the recurrent fragmentation of moist habitats during glacial periods, which are characterized by relatively dry climatic conditions in most of Africa, leading to transient increases of genetic differences between populations followed by secondary contact. At the time of going to press, evidence based on an analysis of mitochondrial D-loop sequences across the entire geographical range of the species, further supported the existence of two distinct clades within the species, corresponding broadly to two subspecies: a clade grouping the populations in East and southern Africa (the nominate subspecies), and a clade for populations in the remainder of the range (*S. c. nanus*, i.e. including *brachyceros* and *aequinoctialis*), with a mean estimated divergence time of 180,000 years (N. Smits *et al.* pers. comm.).

The limited genetic differentiation of Southern Savanna Buffalo *Syncerus caffer caffer* between eastern and southern Africa (Van Hooft *et al.* 2000, 2002) can be explained by a Pleistocene population expansion that started between 270,000 and 37,000 years ago, as indicated by phylogenetic analyses. Furthermore, the genetic distance on the basis of mitochondrial DNA from older lineages in central Africa (Cameroon and Gabon) is indicative of a more precise divergence time of 180,000 to 130,000 years (Van Hooft *et al.* 2002). Taken together, these two observations suggest a recent origin of the Southern Savanna Buffalo. The genetic findings are in agreement with fossil data. These data show that the extinct Reck's Elephant *Elephas recki* and Giant Long-horned Buffalo *Pelorovis antiquus*, rather than the Southern Savanna Buffalo, dominated the African savannas until the late Pleistocene (Kingdon 1982, Klein 1988). The recent origin of Southern Savanna Buffalo is supported by the observation that even African Buffalo fossils from the late Pleistocene represent less advanced forms (Kingdon 1982).

Synonyms: as noted by Ansell (1972), numerous names have been published; Grubb (2005) lists some 55 synonyms. *Syncerus caffer*, from savannas, and *S. c. nanus*, from the rainforest, have different chromosome numbers, namely $2n = 52$ and $2n = 54$ (both with $FN = 60$), respectively (X and Y chromosomes are acrocentric) (Wurster & Benirschke 1968, Gallagher *et al.* 1999), the difference being due to a Robertsonian fusion element. It has been postulated that $2n = 52$ evolved from $2n = 54$. A male hybrid had $2n = 53$ (Cribiu & Propescu 1980), and forest buffalo with karyotypes of $2n = 55$ and $2n = 56$ have been reported. Apparently, a rapid morphological evolution took place (with little molecular differentiation) between the forest and savanna buffalo (Modi *et al.* 1996).

Description A large, dark animal varying in colour from reddish-brown to nearly black with large to very large horns in both sexes. Stocky build, with a short powerful neck. Males have a hump above the withers covering the spines, muscles and ligaments that support the heavy head and horns. Muzzle wide with wet, shining, hairless nose, large eyes and big ears that often droop. Ears fringed with long hairs, and frequently scarred. Pelage generally short-haired and infrequently

Forest Buffalo *Syncerus caffer nanus* adult female.

largely absent. However, juveniles are well haired. Calves are born blackish, or reddish-brown in colour and darkening with age. Adult ♂♂ frequently have skin-folds under the chin, often with hair on it, resembling a beard; also often with a small dewlap. Tail long, with a long tuft of dark hair. They have large, rounded hooves and dew-claws. The dew-claws show-up in the spoor in wet terrain. Buffalo have sweat glands and a characteristic scent, though no specialized olfactory skin-glands (preorbital, pedal and inguinal glands are all absent). Female has a small, rounded udder with two pairs of inguinal nipples. Males, when adult, commonly with a penis-tuft.

In the skull, there are no preorbital fossae and there is no ethmoid fissure. Horns are present in both sexes, and are not ridged. Savanna Buffalo ♂♂ have laterally extending curved horns, inflated bosses and, when adult, little or no hair between the horns; ♀♀ have more slender horns, also laterally extending, with hair on the skin between the horns. Forest Buffalo ♂♂ have shorter horns that do not extend sideways. The tips of the horns often show signs of breakage. Bosses do not form until the ♂ is 3–5 years old. There is no relation between the age of an adult buffalo bull (older than five years) and the gap between the bosses (H. Prins pers. obs.). In the dentition, the fourth lower incisor is the last tooth to erupt at about five years of age. Crown height (see Adaptations) and enamel ridge pattern, together with stages of tooth eruption, can be used for ageing buffalo and results are identical for West, East and southern Africa (Spinage & Brown 1988, Grimsdell 1969, 1973a, Taylor 1988, respectively).

Geographic Variation

S. c. caffer (Southern Savanna Buffalo or Cape Buffalo): *Acacia* savanna, miombo woodland, montane woodlands, highveld and lowveld of eastern and southern Africa, from SW Ethiopia and N Kenya southwards to South Africa and including Uganda, Rwanda, SE DR Congo and parts of Angola. This is the largest subspecies, with the biggest horns and a body weight of 500–800 kg. Strong development of bosses in the horns of the ♂♂.

S. c. brachyceros (West African Savanna Buffalo): Guinea savanna, gallery forests, Sudan savanna and the wettest parts of the Sahel (till approximately the 350 mm isohyet) from Senegal to Cameroon.

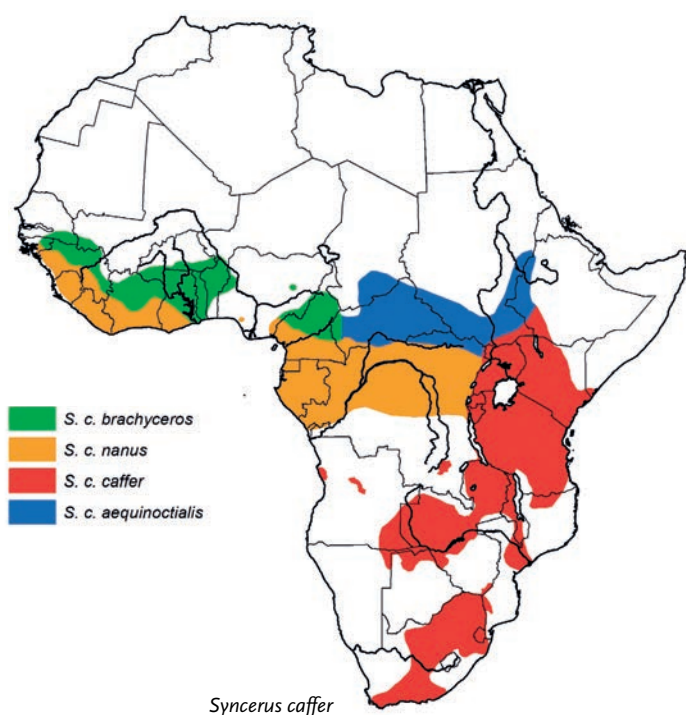

Exact limits with *brachyceros* unclear, but the Chari R. is usually given as the boundary between the two in Chad (Ansell 1972). Horns of this subspecies are more ‘cow-like’ with less well-developed bosses and shorter span in the bulls than in the previous subspecies. Body weight 400–700 kg.

S. c. aequinoctialis (Central African Savanna Buffalo). Following East (1999), this is the form in N Central African Republic, Chad, N DR Congo, S Sudan and W Ethiopia. Little is known about the buffalo occurring in the SE Sudan but they were studied in Dinder N.P. (Hashim 1987). Body weight 400–700 kg, and horns intermediate between the two previous subspecies. This subspecies may include the form *mathewsi* tentatively recognized by Kingdon (1982) from the mountains and uplands to the north of L. Tanganyika, but this form may possibly align with *nanus*.

S. c. nanus (Forest, Dwarf or Red Buffalo): rainforest areas of West and central Africa with an annual rainfall of more than 1500 mm. This is the smallest of the forms, with a body weight of about 250–320 kg. The horns are nearly straight and point backward, with no boss development. Intermediate forms with *S. c. caffer* are known from the area between Queen Elizabeth N. P. (Uganda) and the Ituri Forest (E DR Congo). Buffalo from N Cameroon appear to represent intermediate forms between *S. c. nanus* and *S. c. brachyceros*. Also parts of N Angola appear to contain intermediate forms between *S. c. nanus* and *S. c. caffer* (see Distribution).

Similar Species Water Buffalo *Bubalus bubalis* have been introduced in North Africa (Egypt, Libya, Tunisia) where African Buffalo are absent, and small numbers are used in coastal agricultural lands of East Africa. Similarity in size with Boran bulls (cattle, *Bos taurus*) may cause confusion but generally not with other cattle breeds. The similar, but larger, Giant Long-horned Buffalo went extinct some 4000 years ago (Klein 1994; well-preserved and clear rock engravings known from the Sahara – see McBurney 1960).

Distribution Endemic to Africa. Widely distributed south of the Sahara, though today mainly confined to protected areas. The species has suffered severely from rinderpest (e.g. Van Hooft *et al.* 2002),

and became locally extinct, even in protected areas of Chad, Central African Republic, Cameroon and possibly Congo in the 1990s.

Historical Distribution Formerly the whole savanna zone between Senegal, Gambia and Guinea and Ethiopia and Eritrea, south to the Cape of Good Hope; also the rainforests of central Africa. There is no palaeontological evidence of the species ever occurring in North Africa or in the Nile Valley to the north of Khartoum. There, aurochs (*Bos primigenius*; wild ancestor of common cattle) occupied a similar niche (Gautier 1988), perhaps preventing the buffalo's spread to the north. African Buffalo expanded their range during the last Glacial (see genus profile) and may have increased in numbers with the extinction of possible competitors, such as *Pelorovis antiquus* and *Elephas recki* (Klein 1988, 1994, Prins 1996). Drawings of buffalo are rare in cave paintings, although representations can be seen in Kondoa in N Tanzania (Leakey 1983: pp. 23, 58, 66). In the 1600s, buffalo occurred close to the Cape, as evidenced by local place names (e.g. 'Buffelsbaai').

Current Distribution Despite having suffered drastic declines in numbers across their range, African Buffalo remain widespread, although they now are mainly restricted to protected areas.

West African Savanna Buffalo are now extinct in Gambia, probably occur only as vagrants in Guinea, and the population in Mali's Bafing Faunal Reserve is probably the country's last. In Niger they have disappeared from much of their former range in the south-west and along Nigeria's border, and survive only in W N. P.; their status in Togo is uncertain. Otherwise, their remaining range includes SE Senegal, N Côte d'Ivoire, S Burkina Faso, Ghana, N Benin, parts of Nigeria and N Cameroon.

Central African Savanna Buffalo are now extinct in Eritrea, but still range from SE Chad through N Central African Republic, S Sudan, W Ethiopia (along the Sudan border, where their recent status is unclear) and NE DR Congo (mainly around Garamba N. P.).

Lateral and palatal views of skull of African Buffalo *Syncerus caffer*.

Southern Savanna Buffalo occur in S Ethiopia (particularly Omo-Mago National Parks) and S Somalia southwards and patchily through much of East Africa to Zambia, Malawi, some parts of Mozambique (particularly in the north), NE Namibia, parts of Angola, N Botswana (north of 20° S), and N, NW and S Zimbabwe. In South Africa they have been reintroduced to some of the territories from which they were formerly extirpated; many of these reintroduced animals originate from Addo Elephant N. P. – a naturally occurring relict population in the Eastern Cape that survived the twentieth century (Winterbach 1998). The indigenous population in Swaziland was extirpated, but they have been reintroduced (Monadjem 1998).

The range of the Forest Buffalo in West Africa extends from Guinea-Bissau to SW Ghana, but their status is generally poorly known. In the central African rainforest block, their distribution is from S Nigeria and S Cameroon through SW Central African Republic, Equatorial Guinea, Gabon and Congo (particularly in the north), east to E DR Congo, and south to Angola (East 1999). Historically, there were two large zones of contact between the forest and the savanna buffalo forms in Angola: the plateau south of the high Cuanza R. (areas of Haco and Mussende, Cuanza Sul Province), where Forest Buffalo occurred in the river valley, and Southern Savanna Buffalo in the *Brachystegia* woodland; and Lunda Norte Province, where Forest Buffalo were found in gallery forests, and Southern Savanna Buffalo in the interfluvies. With the exception of Haco, where Newton da Silva (1970) mentioned the presence of hybrids, there is no evidence of hybridization taking place at these contact zones (Crawford-Cabral & Veríssimo 2005).

African Buffalo had colonized Bioko I. (Equatorial Guinea) (Nosti 1950), but they were probably extirpated sometime between 1860 and 1910 due to overhunting (Butynski *et al.* 1997b). They have not colonized islands such as Zanzibar or Mafia.

Habitat African Buffalo inhabit a wide range of habitats, including semi-arid bushland, *Acacia* woodland, miombo *Brachystegia* woodland, montane grasslands and forest, coastal savannas, and moist lowland rainforests. They are absent only from deserts and sub-deserts, such as the Namib and the Saharan/Sahelian transition zone. Although they are not adapted to arid conditions, they can live in semi-arid environments provided they have access to drinking water. Indeed, they are absent from areas without permanent drinking water within about 20 km, and also from areas where there is no permanent grass.

African Buffalo may ascend and descend steep slopes, up to about 50 degrees (H. Prins pers. obs.) and are not uncommon at high altitudes. They are known to be regular visitors on alpine Mt Kenya, where the carcass of a frozen adult bull was found in a glacier at 4700 m (McGregor Ross 1911); they are apparently common visitors to L. Hoehnel (4200 m) and droppings have been seen far up the Teleki Valley at 4150 m (Young & Evans 1993). On Mt Kilimanjaro they are present throughout the forest on the northern and western slopes, and have been observed in the alpine zone up to 4200 m (with tracks at 4500 m) (Grimshaw *et al.* 1995). Interestingly, in the Lent Valley on Kilimanjaro there are shallow caves in which sodium bicarbonate crystallizes, and buffalo enter these caves to chew off the soda deposits; such behaviour has also been observed on Mt Kenya (Grimshaw *et al.* 1995). On this latter mountain the presence of clay and soil-bound iron may explain geophagy (Mahaney 1987).

Forest Buffalo may spend much of their lives in closed forest, and have been found making use of dry caves in the rainforest of Cameroon for resting (C. A. van der Hoeven, P. Beckhuis & H. Prins unpubl.). Yet, most of their foraging takes place in open glades or clearings (Lopé N. P., Gabon, White 1992; Dzanga-Ndoki N. P., Central African Republic, Melletti *et al.* 2007), in open coastal savannas (near Setté Gama, Gabon, Prins & Reitsma 1989) or along man-made tracks (Campo Ma'an N. P., Cameroon, Beckhuis *et al.* 2008), and not in closed-canopy areas. The reason is that *S. c. nanus* is primarily a grazer, too (see Foraging and Food). Kingdon's (1982) suggestion that buffalo evolved in a 'swampy forest' is not supported by these findings. Swamp forests in the equatorial rainforests are typically devoid of grasses or herbs and shrubs such as *Palisota* spp. palatable to buffalo (Reitsma 1988, Blake 2002, Tchouto 2004). Van Hooft *et al.* (2002) on the basis of DNA-analyses suggest an evolutionary radiation of eastern and southern African buffalo out of the Cameroon–Congo–Gabon area. We suggest that the ancestral niche was in open marshy areas in rainforests with grasses and sedges, but especially in the interface between savanna and rainforest and not in a primeval type of rainforest.

Abundance In the most recent continent-wide assessment of the status of African Buffalo populations, East (1999) estimated the total population of Savanna Buffalo at about 830,000 (correcting for undercounting biases in aerial surveys and extrapolating population

densities for areas where no surveys were available). This figure comprises 27,000 West African Savanna Buffalo, 133,000 Central African Savanna Buffalo and 670,000 Southern Savanna Buffalo (although see note under Geographic Variation re distribution limits between *S. c. brachyceros* and *S. c. aequinoctialis*). Winterbach (1998) estimated numbers in southern Africa (excluding Mozambique) at around $111,900 \pm 10,000$ individuals, including 29,300 (± 9000) in Botswana, 48,200 ($\pm 21,000$) in Zimbabwe, 2800 (± 1000) in Namibia and 31,500 ($\pm 10,000$) in South Africa. Numbers of Forest Buffalo are estimated at around 60,000 (East 1999).

In prime habitat *S. c. caffer* can reach superabundance (20 ind/km² in Lake Manyara N. P. in N Tanzania; Prins & Douglas-Hamilton 1990); in other areas, less extreme densities (e.g. Serengeti N. P. woodlands, 8/km²). In prime habitat permanent freshwater occurs every few kilometres and green grass of sufficient quality (i.e. higher than about 7% crude protein) is available throughout the year, but predation risk by Lions *Panthera leo* is very high (Prins 1996). In drier areas *S. c. caffer* attains lower densities: in Tsavo N. P., Kenya, its ecological density (that is, the density within the home-range) was 4/km² (Leuthold 1972) but the crude density (that is, the average density over the whole ecosystem) was only 0.7/km² (Cobb 1976); in the lowveld of South Africa the density is only 2/km² (Funston *et al.* 1994). Numbers were very high in the northern part of Akagera N. P. in Rwanda until the 1990s (H. Prins pers. obs.), but this area has been degazetted and numbers in the park have declined

Horn proportions and shape in different populations of African Buffalo *Syncerus caffer*.

precipitously (Williams & Ntayombya 1999, Apio & Wronski 2011). Most likely the subspecies suffered heavily from civil unrest and war in Somalia, Burundi, Angola and Mozambique.

In West Africa, *S. c. brachyceros* typically occurs in very low densities, but with good protection they can reach higher densities: De Bie (1991) showed that for the 8000 km² Boucle de Baoulé N. P., Sudan savanna of Mali, in normal rainfall years the area could sustain 12,800 individuals and in dry years 2,700, but the present actual number is very small. The number for the whole country is now some 120 individuals only; similar extremely small populations occur in Niger (500) or Nigeria (200) (East 1999). Relative strongholds occur in Senegal (4000), Côte d'Ivoire (8000) and Cameroon (3000) (East 1999). *Syncerus c. brachyceros* is at present absent from Gambia, Guinea-Bissau, Guinea, Ghana and likely Togo (East 1999).

The Central African Savanna buffalo *S. c. brachyceros* occurs in northern DR Congo (39,000) and southern Central African Republic (19,000) with small numbers in Chad (East 1999). Populations in Sudan must have been large in the past: Southern N. P. and immediate surrounds was estimated to contain at least 75,000 buffalo (Boitani 1981). However, not a single animal was observed during recent survey work in this park, although an estimated 10,000 animals were recorded in the Jonglei, predominantly in the northern part of the Sudd (Fay *et al.* 2007), similar to the estimates of Mefit-Babtie (1983). In Eritrea it is extinct, while it is unknown whether the subspecies survives in Ethiopia (East 1999).

In Campo-Ma'an N. P., the total number of Forest Buffalo *S. c. nanus* is less than 0.01/km² because most of this forest has a closed canopy without grass in the understorey (Bekhuis *et al.* 2008). The same holds for Nouabalé-Ndoki N. P. in adjacent Congo (Blake 2002) or in the coastal rainforests of Gabon (Prins & Reitsma 1989). In Lopé N. P., an area characterized by open grasslands within a closed forest (Tutin & White 1998), densities are higher (0.4/km², White 1992). Even in patches of forest within the forest-savanna mosaic of Lopé N. P., their density is quite high (4/km² [Molloy 1997] to 7/km² [Tutin *et al.* 1997], assuming an average body mass of 250 kg); their density is very low in the surrounding closed-canopy forest (L. Korte née Molloy pers. comm.). Forest Buffalo still occur in small numbers in Guinea-Bissau, Guinea, Liberia, Côte d'Ivoire and Ghana; it went extinct in Sierra Leone (East 1999) although buffalo have been reported from Outamba-Kilimi N. P. (L. Korte née Molloy pers. comm.). The subspecies did not occur in the dry 'Dahomey Gap' (Togo and Benin). It is possibly extinct in Nigeria, but occurs in substantial numbers in the forests of Cameroon, S Central African Republic and Gabon; in Equatorial Guinea, Congo and DR Congo numbers have declined substantially due to poaching and uncontrolled hunting (East 1999).

African Buffalo often comprise a major proportion of the biomass of large herbivores if present in a local assemblage. Major competitors are cattle *Bos taurus*, Savanna Elephant *Loxodonta africana*, Plains Zebra *Equus quagga* and Common Wildebeest *Connochaetes taurinus* (Sinclair 1977a, De Boer & Prins 1990, Plumptre 1995, Prins 1996).

Adaptations The cheekteeth of African Buffalo are truly hypsodont ('high-crowned') and the ridges of enamel are sharp, convoluted and well developed to grind siliceous food. Southern Savanna Buffalo individuals about four years old may have crowns that are higher than 5 cm, but constant use wears them down so that

buffalo older than about 18 years have crowns with less than 2 mm enamel without ridges (Grimsdell 1969). Their stomach structure is described by Hofmann (1973) and is well adapted to a grass diet.

African Buffalo can sweat profusely (Taylor 1970b) and the water content of their faeces is high (about 80%, Prins 1996). Their body-water turnover rate is high (King 1979). These features make them rather water-dependent. They have to drink at least every two days, taking about 45 litres daily, and they are not able to survive on the moisture content of their food (Prins 1996). They raise their body temperature only slightly if the ambient temperature rises, in contrast to small dry- and heat-adapted gazelles, and maintain high body temperature during the night, in contrast to eland antelope (Taylor 1970a, b): in other words, they have not evolved water-saving mechanisms. Physiological adaptations include a very thick skin and a trypanocidal protein (a xanthine oxidase) in their blood that kills trypanosomes (Grootenhuys 2000).

Diversity of horn shapes in African Buffalo *Syncerus caffer*. Elevated, heavily bossed and drooping.

In Savanna Buffalo the horn sheaths often extend medially over the intervening frontals. In the ♂♂ the surface becomes conspicuously roughened after some 4–5 years. Particularly in Southern Savanna Buffalo ♂♂, the basal horn sheaths expand medially and anteroposteriorly across heavily roughened frontals that are up-arched to form prominent bosses (Klein 1994). These bosses are not formed in ♀♀, and the intervening skin is covered with hair. When bulls are sparring, they place their bosses against each other, and push. Extensive bossing is a recently derived feature that developed only in the late Quaternary (Gentry 1978, 1990), but not in the *nanus* forms that are thought to be more similar to the ancestral form (Van Hooft *et al.* 2002). Since extensive bossing only occurs in adult ♂♂, it probably evolved through sexual selection, and because it occurs especially in the Southern Savanna Buffalo forms that are characterized by large group sizes, it seems that bossing has evolved in the context of a complicated male hierarchy (see Social and Reproductive Behaviour). The frontal bones under the bosses have a honeycomb structure. The height of the bony walls of the cells is about 15–20 mm, while cell diameter is about 7 mm. Supposedly, this is an adaptation to absorb strong frontal forces while making the head not even heavier than it is, thus maintaining a maximal ability to move the head fast in any direction to confront attack. While the average weight of a dry skull plus horns was 8 kg in Lake Manyara N. P., the heaviest skulls were 16 kg (H. Prins pers. obs.).

African Buffalo have very good eyesight, and they can spot Lions at more than 1.5 km (H. Prins pers. obs.). Their hearing and sense of smell are equally good. They often graze at night, even without moonlight, and where hunting pressure by humans is severe they may become fully nocturnal, and are rarely seen during daylight hours. They can defend themselves very well against predators, and both sexes use their horns as weapons of defence and offence.

African Buffalo *Syncerus caffer* myology.

African Buffalo defend themselves against Lions by taking refuge in dense thickets, standing with their backs to trees and bushes so that the predators cannot reach their vulnerable hindquarters and are presented with a phalanx of dangerous horns. Similarly, in open habitats they will stand and confront predators in a form of group defence (Sinclair 1977a). African Buffalo can run well for short distances, with a top speed equalling that of a Lion, between 55 and 60 km/h, and they can jump about 1.5 m in height. Their skin, in places thicker than 2–3 cm, is so strong that Lion claws often do not penetrate. Because of its sturdiness, buffalo skin was used for making *riempies*, leather thongs, for harnesses of the big *voortrekker* ox wagons of the Boers. Masai used buffalo skin for their large shields.

African Buffalo often attack Lions, and may even attack or chase them when they have spotted Lions at several hundred metres. In particular, African Buffalo will respond to calf distress calls by approaching the location of the call and chasing off the predators (Sinclair 1977a). In such an attack, subadult bulls are most conspicuous but cows and adult bulls frequently join in. Adult Lions may be gored and tossed into the air, and cubs may be completely trampled. Occasionally, African Buffalo show high degrees of curiosity, and may frolic around monitor lizards or large pythons (H. Prins pers. obs.).

They may ruminate lying down in deep water with only their heads above the water, and are partial to mud-wallowing. Both behaviours are likely adaptations to avoid biting insects. Other behavioural adaptations are lying down on bare open places (Prins & Iason 1989) or spending time at high altitudes (Mugangu *et al.* 1995). This may serve as an adaptation to keeping cool by catching a breeze, because African Buffalo do not appear to be well adapted to heat. Buffalo are good climbers, facilitated by their relatively short legs (cf. Klein 1994), and also good swimmers, and can forage under water in flood-plains (Chobe R., Okavango; Botswana; H. Prins pers. obs.).

African Buffalo show clear patterns of activity, alternating between grazing and ruminating. This pattern is subject to seasonal changes in food quality and weather conditions (Lewis 1977, Sinclair 1977a, Underwood 1983, Beekman & Prins 1989, Prins & Beekman 1989, Taylor 1989, Molloy 1997, Winterbach & Bothma 1998). Grazing often takes place in the early morning or late afternoon, but in some areas more than half the grazing can take place at night (Sinclair 1977a, Taylor 1985, Prins & Iason 1989). They may walk long distances between grazing locations, and often walk single file.

Buffalo herds have been recorded covering distances of as much as 8 km in a 24-hour period (Sinclair 1977a, Stark 1986a), although they may be more sedentary in other regions (see Taylor 1985). Adult bulls are often in the front and at the rear of such a file but adult bulls do not take the decision about where to forage (see next section). Their normal walking speed is about 6 km/h (H. Prins pers. obs.).

Foraging and Food African Buffalo are grazers of grasses and sedges, tolerating grass with a high fibre content but preferring grass with moderate protein levels (of about 12% crude protein) and moderate digestibility. They favour sward-forming grasses, such as *Cynodon dactylon*, but also eat broad-leaved grasses, such as *Panicum maximum*. For example, in Serengeti N. P. their selective preference for the soft, nutritious grass *Digitaria macroblephora* was so pronounced that it eventually survived only under thorny *Acacia* bushes. On the shores of L. Kariba, the availability of *Panicum repens* grassland resulted in large herds of buffalo congregating along the shorelines (Taylor 1985). In general, there seems to be broad agreement between researchers as to the plant species recorded in feeding studies made in East and southern Africa (Sinclair 1977a). Various species are avoided or hardly eaten because of low nutritious quality or presence of aromatic oils. African Buffalo only take tussock grasses when the tussocks do not contain too many old stalks, as occurs during the growing season or after burning (see Drescher 2003). The dry season offers much less potential for grazing and then flood-plain species (*Leersia hexandra*) and riverine forest species (*Setaria sphacelata*) become important, while *Cyperus laevigatus* in areas with upwelling ground-water may form a mainstay at that time. African Buffalo sometimes augment their diet by turning to browse.

In most areas little browse is taken (Lamprey 1963, Field 1972, Leuthold 1972, Sinclair 1977a, Hashim 1987, Beekman & Prins 1989, Prins 1996, Halley & Minagawa 2005). Even in the montane forests of Rwanda (Plumptre 1995) and the rainforests of S Cameroon, their diet mainly comprises grass (43%) and Commelinaceae (18%) (Bekhuis *et al.* 2008), but in southern Africa they consume more herbs (Jarman 1971, Mloszewski 1983) as in Gabon (MacLachly 1932). Browse takes the form of green tree leaves (22% of diet in the Zambezi valley; Jarman 1971), or shrubs such as *Grewia*, *Heeria*, *Combretum* and *Euclea* (Kruger N. P., South Africa; Pienaar 1969b), prickly shrubs such as *Capparis tomentosa* (Uganda; Field 1968), and succulent thorn shrubs (Addo N. P.; De Graaff *et al.* 1973). In the rainforest of Campo-Ma'an N. P., African Buffalo consume *Palisota* spp. (pioneer shrubs endemic to the Guinea-Congolian area). These grow as a rule along the edges of logging tracks and roads (Bekhuis *et al.* 2008). Generally, browse is probably eaten to increase the nitrogen content in the rumen and to facilitate fermentation of fibrous grass and especially sedge, which African Buffalo eat in high quantities during the dry season. They produce large amounts of saliva (about 100 l per day, R. R. Hofmann pers. comm.) that is needed to recycle nitrogen from the blood to the rumen.

Optimal conditions for African Buffalo exist when the grass forms swards and leaf height is above 10 cm, as in flood-plains or in forest glades (Prins 1996). In some areas they maintain or create 'grazing lawns' (Vesey-FitzGerald 1969, 1974) and can do this unaided, if the regrowth interval is short enough (Prins 1996). They can create favourable lawns in conjunction with other large herbivores such as Savanna Elephants at L. Rukwa, Tanzania (Vesey-FitzGerald 1960)

or Common Hippopotamus *Hippopotamus amphibius* in Uganda (Eltringham 1999) and Bénoué N. P. in C Cameroon (H. Prins pers. obs.). Grazing lawns have also been reported from Dzanga-Sangha Reserve in S Central African Republic (A. Blom pers. comm.) and some parts of Lopé N. P. (L. White pers. comm.) but seem to be absent from some rainforests because herd sizes are small and densities low. In East Africa, optimal dietary conditions occur during the wet season, while the end of the long dry season coincides with insufficient quantities of food that can be too low in quality to maintain body condition. Where details of diet have been studied in East Africa, African Buffalo appear to be resource-limited (Sinclair 1977a, Prins 1996). During the period with best diet composition there is a peak in calving so that lactating cows can best meet the demands of their calves. The diet of juveniles, subadults, adult cows or adult bulls does not appear to be different. As with many other ruminants, daily dry matter food intake varies between 1.2% and 3.5% of body mass, but this depends on the quality of the food (Sinclair 1977a, Prins & Beekman 1989).

Social and Reproductive Behaviour Populations of African Buffalo consist of discrete herds with a life-span of many decades, and ♀♀ stay in the herd in which they are born (Sinclair 1977a, Prins 1989b, 1996). Most genetic exchange between herds takes place through male dispersal. Yet, gene-spreading cannot be ascribed solely to bulls because mother–daughter inherited mitochondrial DNA spreads as well. This either implies that philopatry in ♀♀ is not absolute or that on a time horizon of centuries female herds may merge (Wenink *et al.* 1998, Van Hooft *et al.* 2000, 2002). Genetic studies clearly suggest that African Buffalo once formed a vast metapopulation with few barriers to gene flow (Van Hooft *et al.* 2002).

Adult cows and their offspring live in stable herds that vary between about 20 individuals in the forest-living *S. c. nanus* (Happold 1973a) to as many as 1000 in *S. c. caffer* in the open savanna of the Serengeti N. P. (Sinclair 1977a, Prins 1989b). Herds of over 2000–4000 individuals have been reported in the past in Lake Manyara N. P. (Park Warden's Report April 1960). It is possible that these very large groupings are temporary associations of two or more herds, because herd home-ranges overlap, and herds can mingle for a while. Savanna Buffalo can also occur in small herds of less than 20

individuals that can be stable entities (Prins 1989b, 1996). In Savanna Buffalo, ♀♀ and their offspring have a rather fixed location in a herd, which means that some individuals are nearly always observed at the rear end of a herd while others frequently occupy a location at the front end of a herd. Such a location may be inherited, because female offspring stay with their mothers well into adulthood. Aggressive (agonistic) behaviour may also play a role in determining position within the herd. Agonistic behaviour consists of hooking and butting with the horns; among ♀♀ this is typically aimed at the flanks or the rump of other adult ♀♀.

In small herds there may be linear hierarchies, but in larger ones hierarchies are much more complicated. Large herds of Savanna Buffalo reveal a fusion–fission society, wherein herds may split for short periods then come together again. This splitting and merging takes place at a time-scale of days and is independent of season (Leuthold 1972, Prins 1989b; see also Cross *et al.* 2005). Possibly, new herds may ultimately arise in this fashion. The herd as a social entity has a much longer life-span than any single individual, and recognizable herds are known to have existed for over 50 years (Prins 1996). Yet, long distance movements by cows have been reported in Botswana, and cows have shown up in different herds. These cows are possibly individuals of low status (Halley *et al.* 2002). Genetic studies show that the migration between herds is only 5–20% for ♀♀ and close to 100% for ♂♂ (Van Hooft *et al.* 2003).

Three types of social organization have been reported for adult Savanna Buffalo bulls, namely (a) permanent herd-bull, (b) non-synchronized alternation between herd state and bachelor-bull state and (c) synchronized alternation between these two states. Forest Buffalo may live in herds with a permanent herd-bull (Dalimier 1955, Blake 2002; the males' tenure duration is unknown). This may be the best reproductive strategy if ♀♀ occur in small herds that are widely scattered in grassy patches within a rainforest that is otherwise inimical to buffalo.

At very high densities with large herds within walking distance from one another, adult bulls of *S. c. caffer* do not show fidelity to the same herd. This occurs in Lake Manyara N. P., Tarangire N. P. and Ngorongoro Crater (Tanzania). There, social organization is one where mature bulls attach themselves to a herd for about two months during which period there is intense competition between many adult bulls for mating opportunities with receptive cows (termed a re-entrant consecutive polygyny). As an individual bull's condition deteriorates, there comes a point (determined by the condition and prowess of the other bulls in the herd) where the previously successful bull moves to the rear of the herd and a few days later he may leave the herd to become a 'bachelor-bull'. He then wanders around alone, or with other adult bulls outside any female herd for days, during which period he recoups his condition. This takes about one month during which period he can wander some 100 km. When he re-enters a herd, this may be the same herd or a different one. Linear hierarchies between bulls do not occur in this system (Prins 1989a). This wandering and re-entering in different herds explains the strongly male-biased gene flow in Savanna Buffalo (Van Hooft, W. F. *et al.* 2003). These two 'reproductive states' may also explain the big differences in testosterone levels between individual bulls during a season (Brown *et al.* 1991). Such a re-entrant consecutive polygyny was also described for Hluhluwe-iMfolozi (South Africa), but with a much shorter cycle (Turner *et al.* 2005).

Profile (left) and frontal (right) views of grazing mouth of African Buffalo *Syncerus caffer*.

African Buffalo *Syncerus caffer*.

A third type of social organization of adult bulls has been described, also for *S. c. caffer*, where buffalo occur at intermediate densities and where herds may be segregated by expanses without surface water, as in the Serengeti N. P. with its pattern of woodlands interspersed with waterless grasslands. Here bulls also alternate between life as herd-bull and bachelor-bull, but these two states are more synchronized between bulls. Most bulls live as herd-bulls during the wet season (about eight months) and in bachelor herds during the dry season (approximately four months). Bachelor herds in this system have a more stable membership than in the previous system and there is evidence of linear dominance hierarchies in both bachelor and herd ♂♂ (Sinclair 1977a). In the re-entrant consecutive polygyny system the average 'bachelor' bull group numbers only about 3.5, which can be explained by a short duration of stay in a group, weighed against the advantages of group formation against the risk of predation. However, the largest groups can still be close to 50 individuals (Prins 1996). In the Serengeti system bachelor-bull groups comprise on average 5–10 individuals, the largest ones about 50 (Sinclair 1977a).

Before the 1960s some buffalo populations may have made more nomadic or migratory movements in response to locally heavy rainfall or droughts so that wet season ranges were in woodlands and dry season ranges in swamps. At present, African Buffalo are increasingly confined to protected areas, and their home-ranges appear to be more fixed. Home-range size varies depending on availability of water and graze. In the Serengeti N. P., Sinclair (1977a) gave home-range sizes as about 220 km², not dissimilar to those estimated in Sengwa Wildlife Research Area, Zimbabwe, of 250 km² (Conybeare 1980). On the other hand, the mean home-range sizes of four herds on the Botswana/Zimbabwe border were 920 km², 1012 km², 1138 km² and 1455 km² (Hunter 1996).

Cows, juveniles and calves stay together in large to very large herds, and even subadults of both sexes stay within their maternal herd. Leaving a herd, even only temporarily, incurs a high predation risk in areas with Lions. When herds move between foraging areas one or more adult bulls may precede them. However, adult cows are quite often in the lead as well. Lead-animals may stop a whole herd simply by not moving on or by giving a stopping signal, which involves standing and blocking the direction of movement. These lead-animals are not to be viewed as 'leaders', that is, as animals that have taken the decisions about where to forage. It gives the appearance of being a communal decision taken by the adult cows in a procedure that has been named 'voting' (Prins 1996). Communal decision-making appears to take place in a number of species, e.g. Sacred Baboons *Papio hamadryas* or Red Deer *Cervus*

elaphus, and may be linked to information exchange as known from several bird studies. In African Buffalo, 'voting' takes place after a long resting bout, typically at the end of the afternoon when nearly all individuals lie down and even have stopped ruminating. Individual cows rise and elevate their head as if staring in a particular direction. The head position is half-way between a resting position (angle of the neck about 30 degrees from the horizontal) and full alert, when the animal has the head elevated so high as if gazing over its nostrils. The voting stance is maintained for a few minutes, after which the cow beds down again, or after which she may start grazing. The vector of all voting directions of individual cows points to the direction of a grazing ground for the night. A short vector implies little consensus within the group of voting cows, while a long vector means a high degree of consensus (that is, all heads were pointing in the same direction). Little consensus is often followed by a temporal splitting of the herd; the resulting subherds then fuse again after a few days.

African Buffalo calves seldom play, and frolicking around is rarely seen. Social interactions between subadult cows are equally rare and restrained. Subadult bulls show intense sparring behaviour, which is also engaged in by adult bulls. During sparring, horns, and especially the bosses, are placed against each other after which the animals start pushing. The 'winner' often is able to hook the 'loser', but the 'winner' seldom pushes his advantage. He stays put so that the 'loser' can try again. Sparring may function as testing dominance between individuals although it looks as if both contestants enjoy the game. Most such interactions between adult bulls appear to be limited to 'sizing each other up' – both bulls look at each other, often observed by other bulls. A more intense form is the parallel walk. Actual fights occur primarily when both contestants are equally strong and big; they are extremely rare and can result in fatal injuries to both bulls.

African Buffalo are generally silent. They occasionally grunt, especially when a cow is hooked by another animal. They snort and cough when alarmed and when they start running. There is a distinct ritualized threat and submissive behaviour amongst ♂♂. Dominant ♂♂ threaten by standing with head up but muzzle pointing down, thus emphasizing the shoulders, a stance characteristic of most bovine species, including the Gaur *Bos gaurus*, Banteng *Bos banteng* and American and European Bison (*Bison bison*, *B. bonasus*). A submissive ♂, when threatened, approaches the dominant ♂ with head held low and parallel to the ground and will often place the muzzle between the hindlegs of the dominant one. At the same time the subordinate animal utters a loud and long bellow, sometimes continuing for the entire duration of the submissive display. The behaviour is similar to that of small calves when suckling or searching for their mother.

This ritualized submission seems unique to African Buffalo; it is not shown by Water Buffalo.

Bulls can make very loud bellows but they usually do this only when badly injured. Other bulls may or may not react to the sound. Whatever the exact mechanism, in about one-third of the instances that a bull is wounded by Lions or hunters another adult bull will come to his aid. Severely wounded animals may also start searching for other buffalo, finding shelter with them. They do not have an alarm call but have a very efficient warning system, especially at night, by becoming dead silent. Then a 'wave of silence' spreads through the bush making it very difficult to pinpoint individual animals in the dark; this may be a safer way of 'sounding' the alarm than focusing attention on oneself.

Mating depends on the willingness of a cow to be mounted. In the hours before an adult bull can attempt this, he shows extensive tending behaviour ('consorting'). When receptiveness increases the bull tries to lay his chin on her tail base. In general, she then walks away, after which the bull tries again. Bulls show flehmen when testing urine of receptive ♀♀. When the cow is willing to stay put, the tending bull is often supplanted by a more dominant bull who then mates with the cow. Prior to that, ♂♂ may mount, and even attempt intromission, but ♀♀ then start running making this impossible. If the cow stays put, then mounting, intromission and ejaculation take a few seconds only. Whether ♀♀ mate with more than one ♂ is unknown, but given the tending behaviour described above, this is unlikely. A recent genetic study provides new insights into male mating behaviour. Y-chromosomal gene diversity decreases significantly between subsequent generations in both Kruger N. P. and Hluhluwe-iMfolozi N. P. (South Africa). This implies either a strong selection effect, possibly related to drought or bovine tuberculosis, or a very small number of reproducing bulls (Van Hooft *et al.* 2010, W. F. van Hooft pers. comm.). The cow remains with the herd to calve, although if the herd moves on the mother and calf may be left behind temporarily while the calf is still weak. Calves may associate with age mates. These associations are especially noticeable in ♀♀ and may last for many years (Prins 1996), as in zebu cattle (Reinhardt 1983). Sometimes these coalitions result in coincident death at a much older age when both 'friends' perish in so-called 'multiple kills' by Lions. Multiple kills in Lake Manyara N. P. comprised about 6% of the kills (H. Prins pers obs.).

Reproduction and Population Structure Across the range, there appears to be a birthing peak during the wet season. In Matusadona N. P., Zimbabwe, conceptions occurred between Dec and May, with births between Nov and Apr, nearly two-thirds of them in Jan and Feb (Taylor 1985). This corresponds to observations in N Botswana (Carmichael *et al.* 1977) and Kruger N. P. (Fairall 1968, Pienaar 1969b). In the more arid Serengeti area there is a clear calving peak, with about 50% of all calves born within seven weeks, but in the more mesic conditions of Lake Manyara N. P. such a peak does not show (Prins 1996). This may also be linked to differences in social organization among bulls (see above). Experiments on captive buffalo bulls in South Africa show a seasonal cycle in testosterone levels, endocrine function and seminal quality; but this cycle is not sufficient to explain a breeding or calving season (Brown *et al.* 1991).

In captive Southern Savanna Buffalo, pro-oestrus lasts two or three days, oestrus one day, and the oestrous cycle from 18 to 22 days (Knechtel 1993). Gestation period is about 340 days (Vidler *et al.* 1963) (similar in captivity; Knechtel 1993). A single calf is born with a mass of about 30 kg; twins are extremely rare. Calves have long suckling bouts of about 10 min when they are some four weeks old, reducing to 5 min when they are six months old (Prins 1996). Calves suckle from the rear; when the dam starts walking with the herd the calf can continue receiving milk but the mother does not lose the protection of the herd. Age of weaning depends on density and intra-specific competition. In Lake Manyara N. P., where the density was high and the population stationary, many calves were still not weaned at 18 months of age, while in Serengeti N. P., where the density was much lower and the population increasing fast, weaning took place at the age of 10 months. Calving interval in Manyara was therefore about 36 months (Prins 1996) and in Serengeti N. P. only 15 months (Sinclair 1977a). Birth rates are thus density-dependent. Calving intervals are not known for the other subspecies.

Individuals are called 'calves' when they do not reach the inguinal fold at its highest point on the flank of the cow. Juveniles are normally weaned and younger than three years (if penis or testicles are not observable it is difficult to establish the sex of a juvenile in the field). Subadults begin to show secondary sexual characteristics and horn shape begins to diverge in ♂♂ and ♀♀: those of cows start extending laterally whereas those of ♂♂ curve strongly upwards, and bosses start to develop. Subadult Southern Savanna Buffalo bulls still have skin covered with hairs between the bosses while adult bulls normally do not. Southern Savanna Buffalo cows begin ovulating after about three years of age, and have their first calf at 4–5 years of age (Grimsdell 1973b, Sinclair 1977a, Taylor 1985). Southern Savanna Buffalo bulls reach sexual maturity at 5–6 years of age, but are unlikely to breed until seven years or older. At that age horns become the typical tools of assault (see Prins 1996 Fig. 4.1). The relation between age and development is not known in the other subspecies.

Foetal sex ratio does not deviate from parity in Kruger N. P., and is independent of rainfall, maternal lactation status, or density (Visscher *et al.* 2004). During dry years, calves are sired by bulls with haplotypes that are different from bulls that sire calves during wet years (Van Hooft *et al.* 2007, 2010). Sex ratio at birth does not deviate from parity either in Lake Manyara N. P., but with increasing age the ratio in herds becomes increasingly slanted in favour of ♀♀ (Prins 1996). Males spend considerable amounts of time outside herds as so-called bachelor-bulls, which may explain this. Indeed, life tables show that mortality patterns across ages in ♂♂ and ♀♀ are similar (Grimsdell 1969, Sinclair 1977a). However, new information reveals that the proportion of bulls in the total population of at least Kruger N. P. shows cyclicity associated with wet and dry clusters of years, and may be as low as 3% during part of the wet cycle and 11% during the dry. This is caused by the birth of proportionally more female calves during a dry period and proportionally more bull calves during a wet period (Whyte 2006). The average age of death (ignoring calf mortality because remains of calves are too rare in the wild) is about 12 years. Maximum longevity in the field is approximately 20 years and in captivity 29 years (Jones 1993, Weigl 2005). Life history parameters for the other subspecies are not known.

African Buffalo *Syncerus caffer*.

Predators, Parasites and Diseases The main predators of Southern Savanna Buffalo are Lions, but predation by Spotted Hyaena *Crocuta crocuta* and Leopard *Panthera pardus* has been recorded, the victims usually being young animals (Kruuk 1972, Schaller 1972, Prins & Iason 1989, Ruggiero 1991, Funston *et al.* 2003). In forest areas such as Mt Meru, Tanzania, predation is insignificant. In Serengeti N. P., predators (Lions) account for only 25% of mortality (Sinclair 1977a). In Lake Manyara N. P., Lion-caused mortality figures are very high, up to 85%, in the absence of major diseases. Thus, the effect of predation depends strongly on location. Little to nothing is known of the relation between predators and the other subspecies.

Lions may take African Buffalo from the midst of a herd, sometimes without other buffalo paying attention while in other instances buffalo go out of their way to kill Lions. There appears to be safety in numbers, even for adult bulls, which are invulnerable when in prime condition. However, Lions often kill old ♂♂ in bachelor groups (Schaller 1972). Usually two or more Lions attack from the rear, and they have to pin the buffalo down otherwise it can shake them off. Sometimes buffalo will try to impale the Lions on *Acacia* thorns. Lions unable to take down a standing buffalo have been seen perched on top of the standing buffalo (H. Prins pers. obs.). If the

buffalo is lying down, they have to suffocate it by holding the muzzle (the 'kiss of death') because they cannot break the neck of even a subadult buffalo. Lions use terrain features as cover to stalk herds (Prins & Iason 1989, Mugangu *et al.* 1995). Other infrequent (less than 5%) causes of mortality include getting stuck in mud, falling down cliffs, or fights with conspecifics. Mass mortality of buffalo after being stampeded by Lions over cliffs has been reported from Zambia (63 and 42 buffalo, respectively) and also mass entanglement in floating grass while trying to cross a lagoon (Anonymous 1965).

Diseases may play havoc with populations of all subspecies. The exotic rinderpest virus first spread through Africa in the 1890s and may have caused mortality in the order of 90% of African Buffalo. Subsequent epizootics have caused major die-offs throughout the twentieth century and the disease is still present in parts of Africa. In the Sudd, S Sudan, aerial surveys have revealed that there is virtually no overlap in local distribution between buffalo and cattle in spite of the habitat being broadly suitable to both species. One explanation is that the buffalo, surviving in inner swamp enclaves, have escaped contact with rinderpest-infected cattle (T. Fison pers. comm.). Indigenous diseases such as anthrax may cause mass mortality at the end of a drought (Prins & Weyerhaeuser 1987). Mortality of calves and juveniles may be caused by infestation with cestodes

and trematodes, and many other diseases, such as tuberculosis, are known to occur in African Buffalo (see Sinclair 1977a, Hoppe-Dominik & Harbers 1988, Prins 1996, Penzhorn 2000). African Buffalo are much more threatened by diseases harboured by livestock than vice versa (Bigalke 2000, Grootenhuis 2000). Once infected, populations maintain reservoirs for bovine tuberculosis (Rodwell *et al.* 2001a, b) or foot and mouth disease (Thomson *et al.* 1992, Ayebazibwe *et al.* 2010): these diseases do not affect them badly. If in contact with disease-free domestic stock, African Buffalo can infect domestic stock, which has major repercussions for the food industry (Bruckner *et al.* 2002) even though foot and mouth disease does not seriously affect cattle (Vosloo *et al.* 2002). A particular type of foot and mouth virus (South African Territories serotype C) may have an ancient association with African Buffalo (Vosloo *et al.* 2002). Buffalo are also known reservoirs of theileria parasites, specifically *Theileria parva lawrencei* (e.g. Young *et al.* 1978), which plays an important role in the epidemiology of cattle theileriosis.

Various investigators have reported on external parasites. African Buffalo from three areas in Ngamiland, Botswana, were found to be infested with *Hyalomma truncatum*, *H. rufipes*, *Rhipicephalus evertsi*, *R. tricuspidis*, *R. simus* and *Boophilus decoloratus* (Carmichael 1976). Horak *et al.* (1983c) recorded several of these species (*B. decoloratus*, *R. simus* and *R. evertsi*) on African Buffalo in Hluhluwe G. R. in KwaZulu-Natal, as well as *Amblyomma hebraeum*, *Haemaphysalis silacea*, *Rhipicephalus appendiculatus*, *R. maculatus* and *R. muelhensii* (and see Horak *et al.* 2007).

Conservation IUCN Category: Least Concern. CITES: Not listed.

In the past, African Buffalo formed a metapopulation at sub-continental scale. They are genetically exceptionally diverse and have not suffered any obvious major population bottleneck over the last several thousand years (Van Hooft *et al.* 2000, 2002). In South Africa its distribution was severely diminished with the advance of white 'trekboers' who, in the late 1800s, roamed the veldt with their cattle in search of ivory. However, numbers suffered their most severe collapse during the great rinderpest epidemic of the 1890s, which, coupled with pleuro-pneumonia, caused mortalities as high as 95% among livestock and wild ungulates (Winterbach 1998). They have repeatedly been hammered by new outbreaks of rinderpest that have spread from cattle to wildlife during the whole of the twentieth century resulting in local extinctions (Branagan & Hammond 1965 – Tanzania and Kenya; Sinclair 1977a – Serengeti N. P.; Prins & Weyerhaeuser 1987 – Lake Manyara N. P.; general overviews Plowright 1982, Prins 1996, Grootenhuis 2000). Mistakenly, officials and farmers blame African Buffalo, rather than livestock, for spreading rinderpest or other diseases such as tuberculosis or bovine pleurosis (Bigalke 2000, Grootenhuis 2000). They still insist on local eradication or 'total control' (KwaZulu-Natal in 2001) of wild animals and especially of buffalo without attacking the root cause, namely the disease reservoirs in livestock of local people. Local eradication programmes, corridor barriers and fencing of protected areas have resulted in a break-up of the initial metapopulation. Roads have a negative influence on large mammal populations nearly everywhere because they facilitate hunting and poaching (Blom *et al.* 2004a) and cause further fragmentation of populations. Increasing agricultural activities and high livestock numbers degrade the areas

between protected areas. There, overgrazing makes the habitat a virtual desert for the buffalo. In Tanzania, for example, the devastating impact of charcoal-burning on local woodlands removes both trees and nutrients, and makes the habitat unsuitable for buffalo (Ludwig 2001). Ever more embattled protected areas thus increasingly become isolated from each other, and in each fragment the buffalo population runs an increased risk of being wiped out by the next major outbreak of disease, especially of rinderpest. In most of rural Africa, programmes for the vaccination of livestock have come to a complete standstill. New strains of rinderpest sweep thousands of square kilometres every decade or so (see Rossiter *et al.* 1987) and in many regions a combination of disease and lawlessness is likely to present a major threat to the future survival of buffalo populations.

Savanna Buffalo populations may suffer from drought. In Masai Mara National Reserve, Kenya, for instance, they declined in numbers by some 60% between 1977 and 2007 (Oguto *et al.* 2011). The drought of 1993 had a devastating impact (Dublin 1994) and was the most severe since 1938 (Mduma *et al.* 1998), yet land use changes, displacement by cattle, and encroaching wheat farming may have been important additional influences (Ottichilo *et al.* 2001, Ogutu *et al.* 2011). Data are insufficient to conclude whether buffalo were affected by the drought of 1970/71 (Van Wijngaarden 1985).

Another threat comes from so-called co-management programmes in protected areas whereby local people and their livestock obtain access to once well-protected parks. Demands by people usually result in overgrazing and pre-emption of grass and water for wild animals, and this affects buffalo in particular. The unfounded beliefs and ideologies of development aid organizations that co-management results in better protection has led to bushmeat poaching and this has had a devastating impact on buffalo numbers. Poaching is not only conducted on a local scale by people living in small villages (FitzGibbon *et al.* 1995), but is often carried out by well-organized companies for meat delivery to towns (Dublin *et al.* 1990, cf. Mduma *et al.* 1998). Policies in which armies and government personnel are allowed to exploit bushmeat together with civil wars are all playing a part in severely decimating local buffalo populations (see, e.g. Plumptre *et al.* 1997). Meat-utilization schemes, as in the Zambezi Delta, were devastating when about 40,000 buffalo were killed in the 1970s (F. de Boer pers. comm.).

African Buffalo can have a high commercial value as trophies, a value enhanced by their having a reputation as one of the most dangerous animals of the African bush. Many private and some communal 'game conservancies' and ranches in southern Africa have restocked with disease-free buffalo and turn a good profit (e.g. Hearne & McKenzie 2000, du Toit 2005). In South Africa, for example, restocking of game reserves and private farms can only be done with disease-free buffalo because of fear of disease transfer from this wildlife to livestock (Condy & Hedger 1978, Grobler & Van der Bank 1996). In fact, disease transfer normally takes place from livestock to wildlife (Bigalke 2000, Grootenhuis 2000). A small remnant population in Addo Elephant N. P. in South Africa provides most of the stock for restocking (Grobler & Van der Bank 1996). African Buffalo have an unrealized potential value due to their resistance (both apparent and inherent) against many tropical diseases that are crippling the African livestock industry. It is likely that their resistance against trypanosomiasis, which is spread by tsetse flies, has a genetic basis (Grootenhuis 1991) and the same may be true for their resistance

against East Coast Fever (theileriasis), which may open avenues for genetic engineering of cattle. The transfer of this genetic asset could speed up the extinction of the donor.

Today around 70% of Savanna Buffalo individuals occur in and around protected areas, with those in East and southern Africa occurring in numerous conservation areas, such as Murchison Falls and Queen Elizabeth National Parks (Uganda), Tarangire and Selous National Parks (Tanzania), Lake Nakuru N. P. (Kenya), Kafue and North and South Luangwa National Parks (Zambia), Mamili N. P. (Namibia), the Okavango Delta and Chobe N. P. (Botswana), and Kruger N. P. and Hluhluwe-iMfolozi G. R. in South Africa. In the rest of the range, numbers of the Western and Central African subspecies are restricted to fewer protected areas, such as Mole N. P. (Ghana), the W-Arly-Pendjari protected areas complex (Burkina Faso, Benin, Niger), the protected area and hunting zone complexes of North Province in Cameroon, Zakouma N. P. (Chad) and Sangha (Central African Republic). About three-quarters of Forest Buffalo occur in protected areas, especially Dzanga-Sangha Reserve (Central African Republic), Nouabalé-Ndoki and Odzala National Parks (Congo), Kahuzi-Biega N. P. (DR Congo) and Lopé and various other protected areas in Gabon (East 1999).

The conservation prospects of the four subspecies of African Buffalo are quite different. The outlook appears good for the Southern Savanna Buffalo *S. c. caffer*, which currently numbers about 670,000 individuals. The Forest Buffalo *S. c. nanus* with some 60,000 individuals is threatened by meat poaching but may benefit from forest clearing. The future of the West African Savanna Buffalo *S. c. brachyceros* with only 27,000 individuals remaining can improve only if the ambitious conservation plans are put into effect (e.g. De Bie 1991). Perhaps most worrisome is the future of the Central African Savanna Buffalo *S. c. aequinoctialis*. Their numbers are thought to be some 133,000 individuals, but the protected areas in their range are to a large extent 'paper parks' only, offering little or no protection (Blom *et al.* 2004b).

Tribe TRAGELAPHINI

Spiral-horned Antelopes

Tragelaphini Blyth, 1863. Cat. Mamm. Mus. Asiat. Soc., p. 164.

Lesser Kudu *Tragelaphus imberbis* frontal view.

Tragelaphines are medium- to large-sized bovines with deep, slab-sided bodies and narrow heads with large ears and twisted horns (hence the name ‘spiral-horned antelopes’). In most species, the ♀♀ are hornless (all except the elands and the Bongo *Tragelaphus eurycerus*), and ♀♀ tend to retain a generic resemblance that is totally absent in the distinctly larger, heavier ♂♂, which have distinctive (but quite variable) horn shapes and darker, more contrasting coat patterns.

Tragelaphini are of undoubtedly Asiatic origin, but have evolved in Africa since diverging from a common root with Asiatic boselaphines some 18 mya when the ‘Proboscidean Event’ marked a solid connection between continents (Hassanin *et al.* 2012). The entire tribe of nine species derives from a single ancestral type, and many, possibly all, species are capable of interbreeding in captivity, most with reproductively viable offspring.

Tragelaphines have slow, tentative gaits, adapted to reduce their conspicuousness, and their elegant, relatively un-muscular limbs are poorly suited to much more than a short rush for cover. Only the more powerfully built elands are endowed with any stamina; the other tragelaphine species prefer to freeze, rush, or slip away or crouch, prostrate, when disturbed.

The colouring of tragelaphines is appropriate not only to a ‘lying-out’ phase in calves, but to crypsis in adult life as a major strategy for escaping predators. It is therefore interesting that tragelaphines are

highly visual animals, relying more on vision and hearing than most other bovines. The transformation of camouflage blotches into vertical lines, which are visually arresting only at close quarters, may be of some intra-specific social significance. Rangy, flat-sided figures and the evolution of crests and manes that effectively extend the visual impact of such patterns serve to enhance this mode of display. Tragelaphines are not territorial and most encounters between male tragelaphines are slow, measured, circling rituals that usually end in one ♂ leaving the scene and fights are relatively rare compared with contests between other antelope ♂♂.

Spiral horns are the product of tensions exerted by the horny sheath upon the traverse of an otherwise straightforward symmetrical bony core inside. Extra keratinous material is laid down along a ‘keel’ and this particular zone of keratin grows at a slower rate than that of the main shaft. This ridge of slower-growing horn drags back growth in the rest of the horn because of its greater mass and the impediment it imposes forces the thinner but faster growing sheath to slew round the main shaft. The details of this differential growth system and its capacity to generate several very distinctive types of spiral horns are discussed further in the genus profile (and see Kingdon 1982).

The differences among tragelaphines manifest an important evolutionary array and they provide particularly apt illustrations of the roles of climate, habitat, food distribution, body size, limb, proportions and social system in determining the peculiarity of species. One of the most interesting of these evolutionary progressions has been the transformation of a tall, Greater Kudu-like ancestral tragelaphine into the massive elands. Kingdon (1982) has discussed and illustrated a selection of these comparisons and evolutionary transformations in some detail.

The skull of tragelaphines is characterized by the absence of preorbital fossae, and the presence of an ethmoid fissure. The teeth are low crowned and, like the digestion, adapted to a ‘gleaning’ diet of young, nutritious vegetation. Glandular secretions are mostly diffuse rather than from highly specialized facial or pedal glands (although inguinal glands are present in some species, for example, Lesser Kudu *Tragelaphus imberbis*). Females have two pairs of nipples.

GENUS *Tragelaphus*

Spiral-horned Antelopes

Tragelaphus de Blainville, 1816. Bull. Sci. Soc. Philom. Paris 1816: 75.

Tragelaphus is a genus that has been split up into several genera or subgenera in the past, based on obvious differences in body size, habitat, tail-type and male–female differences such as possession or absence of horns. Thus, for example, the enormous elands have been included in the genus *Taurotragus*, the forest-dwelling Bongo in the genus *Boocercus* (and also *Taurotragus*), the long-legged, spiral-horned Greater Kudu in *Strepsicerus* and the swamp-dwelling Sitatunga in *Limnocercus*. Several, possibly all species are capable of hybridizing (Boulineau 1933, Jorge *et al.* 1976, Van Gelder 1977a) and producing viable offspring, and molecular studies support keeping all living tragelaphines in the single genus *Tragelaphus* (e.g. Georgiadis *et al.* 1990, Essop *et al.* 1997, Gatesy *et al.* 1997, Hassanin & Douzery 1999, Matthee & Robinson 1999a; and see Hassanin *et al.* 2012), the course that is adopted here.

Thanks to the molecular studies of Willows-Munro *et al.* (2005), the extant members of the genus *Tragelaphus* can now be placed within a single tree with unusually clear lines of descent and plausible dates for divergences between all species. Furthermore, some fossil tragelaphines can also be located, very approximately, within this tree, in spite of known extinctions of prehistoric species.

The entire genus derives from a single ancestor that arrived in Africa between 18 and 14.5 mya. *Tragelaphus* is unknown outside Afro-Arabia and there is abundant evidence to suggest that the modern genus emerged in Africa from an incoming Asiatic boselaphine ancestor (Gentry 1978). That boselaphines gave rise to a parallel lineage in India is supported by the discovery of a Pliocene Indian species, *Selenoportax vexillarius*, which has mixed boselaphine and tragelaphine-like features (Gentry & Gentry 1978).

In the middle Miocene (14 mya) at Fort Ternan, in W Kenya, there are fossils of a medium-sized boselaphine, *Protragoceras labidotus*, which Gentry (1978) has identified as close to the root stock of all tragelaphines. The date of this fossil puts it very close to the first arrival of the putative ancestor of all *Tragelaphus* species. It had a horn structure that provides vital clues to the growth mechanisms that control the diverse spirals typical of all *Tragelaphus* species (Kingdon 1982). Not only does *P. labidotus* serve as a very close approximation to the immediate precursor to the genus *Tragelaphus* in its size and proportions, its ecological context is also of direct relevance in interpreting the tragelaphine radiation.

The mosaic of environments represented at Fort Ternan is thought to have included dry, dense woodland types and semi-deciduous thickets (Bromage & Schrenk 1999). These closed, but relatively dry habitats have a very restricted distribution today but were much more extensive in the past, particularly on the eastern side of Africa (C. Jackson & F. White pers. comm.). It is significant, therefore, that the two *Tragelaphus* species with the oldest pedigrees both inhabit thicket country in north-east and south-east Africa. According to the molecular analysis of Willows-Munro *et al.* (2005), the Lesser Kudu *T. imberbis* is the most conservative species in the genus. Its earliest branching as an identifiable lineage has been calculated, by Bayesian molecular clock, as being in excess of 12 mya. When the skull of this species is compared with that of *P. labidotus* there are striking similarities, both in the long face, tooth structure and cranium. A

Sitatunga *Tragelaphus speki* male head frontal view.

detailed reconstruction of *P. labidotus* (Turner & Anton 2004) suggests a long, slender neck, like the Lesser Kudu, but shorter, more stocky legs. The one respect in which they are emphatically different is in the structure of their horns, the details of which will be discussed shortly.

The limb and neck proportions of the Lesser Kudu differ from those of its closest affine, the Nyala *T. angasii*. The latter is stockier, and has a shorter neck and shorter legs, but is otherwise of similar size and habits. The colouring and body markings of immature Nyala ♂♂ are almost identical to those of Lesser Kudu ♂♂, but the horns are loose, open lyres compared with the tighter spirals of the Lesser Kudu. The two species show a mosaic of similarities and differences and this is typical of *Tragelaphus*. While most species exhibit distinct ecological preferences, the *imberbis*–*angasii* pair have a broad ecological equivalence in spite of living in different hemispheres. It is possible that the north/south divide could reflect an attachment, by the more conservative of the two, to the region of earliest adaptation, whereas the Nyala, further from the tragelaphines' north-east African 'homeland', represents a later isolate of the same basal stock. In the light of their genetic pedigrees, both species can be regarded as

Tentative phylogenetic tree of tragelaphine radiation (in part after Willows-Munro *et al.* 2005 and Hassanin *et al.* 2012). Note that SE and centre-west *Tragelaphus scriptus* might have separate or genetically mixed origins.

little-changed representatives of basal *Tragelaphus*: marginally altered 'living fossils'.

In the discussion that follows, the phylogenetic tree and estimated dates of Willows-Munro *et al.* (2005) are used as the format for an ecological and biogeographic interpretation of the subsequent radiation of *Tragelaphus*. Unlike some students of antelope evolution, I do not look only to global climate changes to explain branchings within trees or morphological innovations, but rather seek intra-continental geographic separations between established populations that, at the grossest level of generalization, might have isolated populations at high or low latitudes, high or low altitudes, north/south, east/west, or some such equivalent. For example, ever since the Oligocene, habitats surrounding the Sahara have been consistently drier and more open whereas more equatorial and south-easterly habitats have tended to be warmer, wetter and less open. Over long periods of time, each wing of an originally common *Tragelaphus* population would have adapted to some dominant features of their habitat. If climate changes subsequently favoured one or other population, it may well have expanded its range, while the other retreated. Yet another climate change and the trend could be reversed. Notwithstanding such expansions and contractions each population was likely to have continued to flourish best and be most numerous at the heart of its earlier 'homeland'. This may help explain why archaeo-tragelaphines such as the Lesser Kudu and Nyala have survived so long with apparent minimal change. Thus, the tragelaphine preference for rather dry woodlands has persisted from their earliest beginnings right up to the present while their expansion into wetter types of closed forest or swamp, or to very open habitats, was more recent. The pattern of moving from drier to wetter and more equatorial regions is an evolutionary trend that is discussed in more general terms elsewhere (Volume I, pp. 51 & 84).

The first major split in *Tragelaphus* began, about 10 mya, between a lineage that maintained a preference for more closed habitats and one that shifted into more open woodlands. Animals in more exposed environments have to become more mobile and increased exposure

Greater Kudu *Tragelaphus strepsiceros* skeleton.

to predation favours an increase in both body size and group size as well as horns on ♀♀. The open woodland lineage has culminated in the two eland species and it is significant that the more conservative eland species, the Giant Eland *T. derbianus*, still occupies the dry woodlands immediately south of the Sahara. Of this 10-million-year-old bifurcation the more conservative branch is today exemplified by the Greater Kudu *T. strepsiceros*, which has an emphatically southern, closed-habitat distribution. It is therefore plausible that the primary divide between ancestral elands and ancestral Greater Kudu was a north-south one. Like the elands, Greater Kudu have reached gigantic proportions in the past but it is likely that the size of the Greater Kudu (as with other tragelaphines) may well be relatively labile, with gigantism being a response to periods of unusually favourable conditions when dietary, competitive or other constraints were temporarily lifted. None the less, Greater Kudu live up to their name and have remained among the largest bovines and have probably always depended on dense cover and prodigious jumps to make effective getaways from large predators.

A wide north-south divide, possibly linked with initial differences in temperature-tolerance, body size and behaviour, may have a bearing on the next phylogenetic divergence, which took place at about 9 mya within a very early population of the *T. strepsiceros* lineage. This offshoot might have begun as the northern wing of a predominantly southern stock, but its primary innovation was to become the first *Tragelaphus* species that was a true ecological 'generalist', not the thicket specialist that so many of its precursors had been. Judging from their living descendants, previous *Tragelaphus* lineages had retained an attachment to dense, dry woodlands (or, in the case of elands, evolved a 'giant' strategy to move into more open habitats). This new lineage retained its dependence on dense vegetation for refuge, but could survive in a very broad spectrum of habitats including open/

Sitatunga *Tragelaphus spekii*.

closed mosaics at a variety of altitudes and latitudes. Its success was based on a broad climatic tolerance, together with early maturity, exceptional fecundity, and cohesive social groups (which we can extrapolate were based on small numbers of closely related ♀♀). This was the lineage that ultimately gave rise to all the remaining *Tragelaphus* species and its relictual survivor is the Mountain Nyala or Gedemsa *T. buxtoni* (which is threatened by the near-indifference of current authorities to the conservation of Ethiopia's unique fauna and flora). This species shows many resemblances with a Pliocene fossil from North Africa, *T. gaudreyi*, which may represent a 'chronospecies' belonging to the same lineage. There are more dispersed fossils that are consistent with a very wide distribution of this lineage during the Mio-Pliocene. In the late Miocene, when the *buxtoni*–*gaudreyi* lineage first emerged, most antelope lineages were still at an early stage of their radiation and ancestral buffalo had yet to arrive. Some of the most lethal predators were also absent, so a combination of less predation and less competition could have facilitated a wide spread of the *buxtoni*–*gaudreyi* lineage through many habitats. Contemporary restriction of the sole survivor of this lineage to cold uplands in S Ethiopia is less the mark of a super-specialist than a measure of the breadth of its one-time adaptive range. This history must qualify the justifiable description of the living species as a 'montane specialist'. Like the Lesser Kudu and Nyala, it is a living fossil, a magnificent has-been, left over from a long career as one of the more splendid and widespread of Africa's Mio-Pliocene bovids.

However, as competition and predation increased, decline of the Mountain Nyala lineage must have been linked with such disadvantages as large body size, the need for a rich diet, very limited stamina and a rather rudimentary form of social coherence. Under these circumstances there probably has been selection for smaller, more agile animals that were better able to escape or conceal themselves. Possible descendants of this type of selection are the many, fragmented, but hugely successful populations of the Bushbuck *T. scriptus*. Bushbucks could be descended from the *T. buxtoni* lineage or, much earlier, from *T. angasii*.

Among the many habitats that the Mountain Nyala lineage moved into was the equatorial rainforest and it was here that pressure from predators and a scarcity of low-level palatable herbage selected for two very different types of 'forest tragelaphine'. Rivers and swamps lace all African forests and, for any large herbivore, represent a very effective refuge from predators because they are heavily obstructed

and full of impediments for a carnivore: notably water and mud. For a variety of reasons, swampy areas also tend to offer more browse than is available under a closed forest canopy. It is very likely that the ancestors of Sitatungas *T. spekii* were animals that initially used swamp-forest as a refuge, then adopted it as a habitat and finally became swamp specialists both within and outside the forest belt.

Swamp forest can be characterized as the bottom end of the forest catena: the 'top' or outer end can be taken as the forest edge and because African forests are in a constant state of flux and fragmentation, edges are very numerous, particularly along the outer, northern margins, but also within the forest wherever clearings or tree-fall chablis have formed. Along these forest margins the main resource, for a large browser, is low-level herbaceous, vine, young tree and shrub growth, all of which need sun. Because every gap is soon filled and the forest edge is forever advancing or retreating, large browsers need to be very mobile and cover a lot of territory, some of which is poorly known. Under these circumstances largish group sizes and horned ♀♀ provide some deterrence to predators. In these respects, a large forest browser faces similar challenges to those facing proto-elands in drier, more open woodlands.

In adapting to the specifics of this habitat the ancestors of Bongos *T. eurycerus* have paralleled the elands in some respects, such as ♀♀ developing horns, but they have modified the proportions of their legs and horns in ways that are typical of other forest-dwelling herbivores. Like forest Bushbucks, Nyalas and Sitatungas, the female Bongos are bright red with stripes and even ♂♂ have predominantly red colouring.

Differences in *Tragelaphus* horn shape have long confounded taxonomists who wanted to use this as a diagnostic feature. In fact, horn shapes vary enormously within species and many throw up aberrant twists and splays whose ontogeny helps reveal why the spirals of these 'spiral-horned bovids' can respond so readily to selection.

To return to *Protragocerus labidotus*, the putative boselaphine ancestor of all *Tragelaphus* species. This species had short 'bladed' horn cores that twisted into the beginnings of an incomplete spiral. Paired blades or keels arose on the top of the horn cores, near the crown, swept up and back before turning in again. A second, less distinct keel began at the back of the horn, just behind the eye socket and its traverse, upwards and inwards, was much less marked. Another African boselaphine, probably a descendant of *Protragoceros*, *Mesembriportax acrae*, had such prominent anterior 'keels' that Gentry

Outline of *Tetracerus* skull indicating positions of four horns (left), compared with outlines of skull of Early tragelaphine, *Protragocerus labidotus* with bladed horns (right).

Bongo *Tragelaphus eurycerus* horn cores in subadult male showing eminence on horn core (vestigial trace of 'branched' horn).

(1978) suggested that the horn sheaths might even have bifurcated at their tips, like the American Pronghorn *Antilocapra americana*.

Young male *Tragelaphus* show the rudiments of these boselaphine 'keels' or anterior horn 'blades'. One takes the form of a small, elongated bony excrescence or bud on the newly grown horn shaft and it is situated on the crown, just above the eye. The other, as in *Protragocerus*, is little more than an angled edge under the horn shaft and behind the eye. But for their vestigial excrescences, the sheaths of newly sprouting *Tragelaphus* horns would approximate to a symmetrical cone of bone sheathed in keratinous 'horn'. The bony core would grow like a straight, pointed wand, were it not for its straitjacket of keratinous horn. Were the keratin laid down as evenly and consistently

Bongo *Tragelaphus eurycerus* growth rings on spiralling horns.

around the bony core, as is the case in *Oryx* and *Pelea*, tragelaphine horns would be just as straight. Instead, young, fast-growing tragelaphine horns almost immediately begin to be deflected from any such trajectory and the main cause of that deflection is a slower rate of horn growth at the two keels (where thicker layers of horny keratin are laid down). The traverse and shape of *Tragelaphus* horns is therefore mainly the product of an interaction between an approximately 'would-be straight' bony shaft and its enclosing horny sheath. It is the latter that pulls the malleable core into a spiral because the rate of sheath-growth around the shaft is as consistently uneven as calcium deposition around a soft-bodied mollusc or spiral-shelled snail (Wentworth Thomson 1942). However, the horn cores of most tragelaphines do not have perfectly symmetrical, circular cross-sections, and this is probably because such primitive symmetry was already compromised in ancestral, boselaphine cores, with their flat-edged keels. Thus, some species tend to combine a rounded section with a slower growing section that is flatter. There seem to be no obvious phylogenetic implications here, thus the conservative Nyala and more derived Bushbuck, Sitatunga and Bongo all have bladed spirals. In other species, the flat section between the two keels disappears because the lower keel is suppressed to a greater or lesser degree. When this happens the horn acquires a more rounded section and it is the single upper keratinous ridge that pulls the horn into a corkscrewing spiral. This type of horn is shared by Lesser and Greater Kudus, both eland species and the Mountain Nyala.

Aberrant Greater Kudu *Tragelaphus strepsiceros* with cylindrical cross-section to non-spiral horns (right). Normal cross-section shown on left.

That the very few determinants of horn shape (more or less material accreting at upper or lower keel, or around the core, thicker or thinner shaft, rounder or less symmetrical cross-section) are each subject to continuous variation is evident in the existence of much individual variation. Natural selection for a particular conformation therefore operates with a rather small number of genetic permutations and much natural variation. This may help explain why change can be rapid and relatively close relatives need not have very similar horns. For further discussion of this topic see Kingdom (1982).

Tragelaphus imberbis LESSER KUDU

Fr. Petit Koudou; Ger. Kleiner Kudu (Kleinkudu)

Tragelaphus imberbis (Blyth, 1869). Proc. Zool. Soc. Lond. 1869: 55. 'Abyssinia'; now known to be Ethiopia, Shoa Prov.

Lesser Kudu *Tragelaphus imberbis*.

Taxonomy Two subspecies have been named, but distinctive characteristics and geographical separation between the two forms are unclear (Ansell 1972). Synonyms: *tendal*. Chromosome number: $2n = 38$; the karyotype is unusual in that X and Y chromosomes are each fused with one of two identical autosomes (similar to situations in other *Tragelaphus* spp.; Benirschke *et al.* 1980).

Description Medium-sized antelope with 10–14 vertical white stripes on the sides. Neck with two white patches, one just below throat, one at the base; there are several small white spots, mainly on the hindquarters. Face fairly dark, with two oblong white spots in front of the eyes and two small white spots on each cheek. Muzzle is blackish with white sides; chin white. Ears are large and rounded.

There are contrasting dark patches on the inside of the legs above the 'knees'. Tail is bushy, white underneath, with black tip. Stripe pattern and throat patches vary individually to some extent. Back horizontal, in contrast to some relatives (e.g. Bushbuck *Tragelaphus scriptus*). There is one pair of inguinal glands; there are diffuse scent glands around the false hooves on the hindfeet (Pocock 1918). There is pronounced sexual dimorphism: the ♂ is considerably larger, with a much thicker neck, darker in colour, and more purplish-grey; the ♀ is a rich rufous-brown, more greyish on the neck. There is a dorsal crest of hair along the neck and entire back of ♂♂, most pronounced over the shoulders; in ♀♀, this crest is much less developed. In contrast to the Greater Kudu *T. strepsiceros*, there is no mane of hair on the underside of the neck (cf. 'imberbis' = beardless). Females have two pairs of inguinal nipples.

Lesser Kudu *Tragelaphus imberbis* myology.

Horns present in ♂♂ only, dark brown with whitish tips, spiralled, but more narrowly and with smaller spread than in the Greater Kudu.

Geographic Variation

T. i. imberbis (including *tendal*): Ethiopia and Somalia (and probably also Sudan and Uganda).

T. i. australis: Kenya and Tanzania.

Similar Species

Tragelaphus strepsiceros. Geographic range much larger, with 'centre of gravity' in southern Africa, rather fragmented in East and central Africa. Sympatric with the Lesser Kudu in large parts of the latter species' range. Adult ♂ considerably larger, with longer and more widely spread horns and dense fringe of hair along underside of neck; young ♂ and ♀ larger, general colour more greyish, vertical stripes less distinct, more widely spaced, fewer in number. Legs slightly longer in relation to body. Female with more pronounced shoulder hump and dorsal hair fringe. No white patch at base of neck, only on throat, but less distinct.

Distribution The Lesser Kudu is largely confined to the Somalia–Masai Bushland BZ or the 'Horn of Africa'. Historically, this species ranged from ca. 12°N in the Awash area of Ethiopia southward through S and E Ethiopia, much of Somalia except the north and north-east (i.e. east of 46°E and north of 08°N), most of Kenya except the south-west, extreme SE Sudan, NE and E Uganda, to NE and C Tanzania (Leuthold, W. 1979, East 1999). The southern limit lies in or near Ruaha N. P. in Tanzania (Leuthold 1979a), at ca. 08° 30'S, and they are also recorded from the woodland zone of the Udzungwa Mts (Rovero & De Luca 2007). Its former occurrence in N Eritrea has also been reported, but is not confirmed. The exact limits of distribution are not well known, partly perhaps because of occasional confusion with the Greater Kudu, with which it shares much of its range.

Lateral, and palatal views of skull of Lesser Kudu *Tragelaphus imberbis*.

Tragelaphus imberbis

Within recent history the range has probably not changed much, except locally. In Djibouti, where the Lesser Kudu may have occurred formerly in the south-west, its presence has not been confirmed recently (Künzel *et al.* 2000, Laurent & Laurent 2002, Heckel & Rayaleh 2008). In Somalia, numbers have probably decreased since the 1980s, and there is no information that it survives in the central or north-western parts, though it apparently still occurs widely in the south (East 1999). In Sudan, Fay *et al.* (2007) confirmed its continued presence in the southern section of Boma N. P. In Uganda, it probably now only survives in the eastern part of South Karamoja Controlled Hunting Areas (East 1999).

The purported former occurrence of this species in the Arabian Peninsula is based on a single set of horns obtained in 1967 from an animal reputedly shot in Jabal Halmayn, south-east of Dhala, in S Yemen, and another specimen shot at Nuqrah in Saudi Arabia around

Lesser Kudu *Tragelaphus imberbis*.

1968 (Büttiker 1982, Harrison & Bates 1991). No live animals have ever been reported from the area, and the true origin of those specimens remains in doubt though they probably originated from animals that escaped from private collections.

Habitat The Lesser Kudu inhabits semi-arid areas with medium to dense woody cover, including riverine forest and thickets; it generally avoids open spaces and long grass (cf. Fig. 9 in Lamprey 1963). In its geographic range, this means mainly *Acacia-Commiphora* woodlands and vegetation derived from these, in areas characterized by low and erratic rainfall and long dry seasons. Largely confined to lowland areas up to ca. 1200 m (Stewart & Stewart 1963), the animals do occasionally climb hills, for example, in search of specific food sources. Recorded up to 1600 m in Ethiopia (Yalden *et al.* 1996), and observed on farmland near Ol Molog at about 1740 m near Mt Kilimanjaro (Grimshaw *et al.* 1995). Small-scale seasonal movements related to changes in vegetation condition and availability may result in some concentration of the animals near rivers in the dry season, probably more on account of the vegetation there than the water (Leuthold, W. 1979). Availability of free water does not appear to be essential.

Abundance Because of its habitat preferences, its cryptic behaviour and a somewhat clumped distribution the Lesser Kudu is very difficult

to census, both from the ground and from the air. Available estimates of density and/or total numbers are therefore difficult to evaluate.

Ground counts in Tarangire N. P., Tanzania (Lamprey 1964), and Tsavo East N. P., Kenya, produced density estimates of 0.2–0.3 animals/km², with maximum values of ca. 1/km² in the most favourable habitat (Leuthold & Leuthold 1976). Figures from other areas generally fall within the same range, but East (1999) mentions local densities of 0.5–3 animals/km². Extrapolating from these values, and using a correction factor for undercounting, East (1999) derived a total population estimate of ca. 118,000 animals for the entire range of the Lesser Kudu.

Adaptations The Lesser Kudu shows few specific adaptations to its habitat and way of life. Being rather slender, the animals move easily through dense bush. In situations of possible danger the animals 'freeze', sometimes keeping a foreleg lifted in mid-air, while fixing the source of alarm. This behaviour enhances the cryptic effect of the vertical stripes in dense bush. The camouflage is most effective in the dry season, when the entire vegetation has a drab greyish-brown aspect. Upon being seriously alarmed, they often utter a loud bark, which may be important as a signal to conspecifics, as may be the curling of the tail while running. This exposes the white 'brush' on the underside that serves as a visual signal. Like Greater Kudus, they are accomplished jumpers.

Because of its closed habitat, activity patterns of the Lesser Kudu are difficult to study: data are limited to some incidental observations by Leuthold, W. (1979) and a very brief study by Mitchell (1977) in Tsavo East N.P., during daylight hours only. Overall, foraging takes up about 35% of the animals' time, being concentrated somewhat in early morning and late afternoon. Resting, with or without ruminating, is most pronounced during the middle of the day, when the animals often move into the shade. Activity patterns on single days vary considerably, but tend to show an alternation between feeding and ruminating bouts, as in other ruminants (Leuthold 1977).

The choice of food, including leaves of succulent plants and some fruits, also constitutes an adaptation to the dry environment in that it renders the animals largely independent of free water. Size and structure of the stomach also reflect the strong preponderance of browse in the food (Hofmann & Stewart 1972). In particular, the relatively small rumen, the large reticulum and small omasum characterize the Lesser Kudu as a 'tree and shrub foliage eater' consuming food with a high fermentation rate and quick passage through the digestive system (Hofmann 1973).

Foraging and Food The Lesser Kudu is primarily a browser (Hofmann & Stewart 1972, Cerling *et al.* 2003), consuming mainly leaves of trees, shrubs and herbs. Flowers and fruits may also be taken when available. Grasses are eaten only in small quantities and in early growth stages, i.e. mainly in the wet season. The range of food plants is very broad: 118 species were identified in Tsavo N. P. (Leuthold, W. 1979). A few additional species were found in the stomach contents of animals from other parts of Kenya (Hofmann 1973).

There are considerable seasonal and local variations in the composition of diet. Local variations reflect the composition of the vegetation and thus differential availability of plant species. Seasonal variations reflect vegetation condition, which depends mainly on rainfall. Leaves of trees and shrubs make up 60–80% of the food at all times. The leaves of creepers and vines (e.g. *Thunbergia guerkeana*, some species of Cucurbitaceae and Convolvulaceae) and herbs constitute 15–25% during the wet season, but become insignificant as they dry up. Fruits of various trees and shrubs are eaten mainly in the dry season, which may reflect their availability, but may also be related to their water content.

Within the category of trees and shrubs the species composition also changes considerably between seasons. The most important wet-season food plants include mainly deciduous species, whereas in the dry season some evergreen shrubs predominate (Table 5 in Leuthold, W. 1979). The latter do not seem to be preferred, if there is more choice, but some of them are important as dry-season staples (e.g. *Salvadora persica*, *Thylachium thomasii* and *Boscia coriacea*). As these evergreen species are also eaten by other browsers, particularly Gerenuk *Litocranius walleri* and Giraffe *Giraffa camelopardalis*, there is considerable potential for competition in the dry season (Leuthold, B. 1978b). Selectivity with respect to plant parts can be inferred from the animals' searching behaviour: they 'sniff over' a potential food plant extensively before taking a bite.

Olfactory searching is also employed to find fallen fruits under trees (e.g. *Melia volkensii*). These resemble unripe walnuts in size and shape and are chewed at some length, the large seeds generally being dropped. Fruits of *Acacia tortilis* and some other species are also picked up from the ground; the searching behaviour could easily be mistaken

Lesser Kudu *Tragelaphus imberbis* exposing white brush on underside of tail.

for grazing (Fig. 11 in Leuthold, W. 1979). Much smaller fruits (e.g. *Commiphora* spp.) are often plucked directly from the trees.

Root tubers of *Thunbergia guerkeana*, when found by chance, appear to be highly attractive, presumably on account of their water content. Animals jockey for positions providing access to a root tuber and sometimes are overtly aggressive toward conspecifics. Also, animals may drop onto their carpal joints for better access, a behaviour not seen otherwise in the Lesser Kudu.

Very few species of trees and shrubs appear to be rejected entirely as food by the Lesser Kudu. Among these is *Platycephalum voense*, a widespread and prominent tree in Tsavo N. P. In addition, some species of *Acacia* with very small leaves are not eaten, possibly because of their thorns, the Lesser Kudu being less well equipped to cope with these than, for example, the Gerenuk or Giraffe.

By stretching head and neck upward an adult ♂ can reach up to ca. 2 m, a ♀ ca. 1.8 m. Occasionally, an animal tries to reach even higher by lifting one foreleg and/or by 'angling' with the tongue. Rising up on both hindlegs, as the Gerenuk commonly does, was never observed in the field.

Lesser Kudus do drink from open water, but rarely. In parts of their range there may be no free water for extended periods of time. Water requirements can largely be fulfilled from the water content of the food plants, particularly from succulents like *Sansevieria* spp., *Euphorbia* spp., fruits, or the root tubers referred to above.

Social and Reproductive Behaviour In Tsavo East N. P., Lesser Kudus live singly or in small groups numbering 2–6 animals, and occasionally up to ten. Larger groupings are usually temporary associations of two or more groups. Mean group size varies locally and

seasonally between 2.0 and 3.6, but the largest 'group' seen included 24 animals. Single animals are most often ♂♂, adult or subadult. The latter may also join up in small groups, whereas fully adult ♂♂ apparently do not. Single ♂♂ or male groups often associate with groups of ♀♀ and young (Leuthold & Leuthold 1975a).

Variations in the stripe pattern permit observers to recognize individual animals and thus facilitate the study of group composition and stability. 'Nuclear groups' of one to three ♀♀ and their young remain stable over fairly long periods of time (three known ♀♀ stayed together for at least four years). They may join up with other such groups and/or with ♂♂ temporarily, which accounts for the great variation in group size and composition (Leuthold, W. 1979).

Individuals or stable groups inhabit home-ranges measuring 1–6 km² and overlapping considerably between individuals, even adult ♂♂. The latter are apparently not territorial; there seems to be a hierarchy among adult ♂♂ living in the same area, which tend to avoid close contact. This explains the lack of field observations of serious agonistic encounters.

Behavioural elements seen in 'tense' situations include erecting the dorsal hair crest, stiff-legged 'determined' walking, brief rushes and actual chases of opponents. Also prominent is shrub-horning during and/or after such encounters. Actual fighting techniques, observed only among subadult ♂♂ at a toned-down level ('playfighting') are similar to those of many other bovids (for observations in captivity see Walther 1964a). The shape and structure of kudu horns entail a certain risk of their becoming inextricably interlocked, which is likely to result in the death of one or both contestants (cf. Fig. 23 in Leuthold 1977). Agonistic behaviour of ♀♀, relatively rare, involves a short rush and/or butting with the forehead against the head or side of another animal.

Lesser Kudu *Tragelaphus imberbis* courtship behaviour.

The few observations on courtship behaviour made in the field agree largely with those on captive animals (Walther 1964a). The ♂ approaches the ♀ from behind in a pronounced low-stretch posture. If the ♀ urinates, the ♂ almost invariably shows flehmen. He may then move forward alongside the female's flanks, still in low-stretch, perform gasping movements with his lips and rub his head on her sides and neck (cf. Figs 36 & 37 in Walther 1964a). This may be accompanied by low vocalizations barely audible in the field. When mounting, the ♂ rests his head and neck on the female's back, as other tragelaphines do.

A ♀ about to give birth usually separates from her group. The mother–young relationship follows the pattern typical of young bovids of the 'hiding' type (cf. Leuthold 1977). While the young animal remains behind, lying quietly, the ♀ moves off to feed. She returns periodically, mainly in the evening, to suckle the young. In this context, mother and young apparently communicate with low

Lesser Kudu *Tragelaphus imberbis*.

bleating vocalizations also heard in a young captive animal (Leuthold & Leuthold 1973). During or after suckling, the ♀ licks the young, particularly its perineal region, and may consume its urine and/or faeces. At 3–4 weeks of age the young starts to follow its mother more and more, and may then join her original group with her.

Behaviour with social and/or communicative functions, such as mutual grooming, is rarely seen in free-ranging Lesser Kudus, in contrast to captive animals (Walther 1964a). A visual signal, curling the tail upwards and spreading the white hair on its underside, is shown whenever an animal runs, regardless of context. In situations of alarm a loud bark is uttered, but barks may also serve to signal an individual's position to conspecifics (Kingdon 1982). Young animals bleat loudly when in distress. Olfactory signals do not appear to play a prominent part in communication of the Lesser Kudu.

Associations and interactions with other ungulate species are relatively rare, in some contrast to the situation in more open habitats. The Lesser Kudu is seen occasionally with Gerenuk or Impala *Aepyceros melampus*, which may both utilize the same habitat type. In two instances a Lesser Kudu and several other ungulates were aggregated under a fig tree *Ficus sycomorus* in which baboons (*Papio* sp.) were feeding and dropping fruits that were then collected by the ungulates (Leuthold, W. 1979).

Reproduction and Population Structure Lesser Kudu young may be born throughout the year, both in the wild and in captivity (Lang 1976, Leuthold, W. 1979, Váhala 1992). Individually known ♀♀ in Tsavo N. P. gave birth at intervals of 9–10 (Leuthold 1979b) months; inter-birth intervals in captivity clustered around 250–270 days (Váhala 1992). The gestation period is ca. 32–34 weeks (e.g.

Dittrich 1972), but is not well documented. Females reach sexual maturity at 1–1.5 years, ♂♂ at 1.5–2 years of age; in wild ♂♂ reproduction probably does not begin before the age of 4–5 years when they reach social maturity. Birth-weights are ca. 5–7 kg in ♂♂, slightly less in ♀♀. One young is born at a time; as an exception, twin births occurred in an American zoo in 2001 (E. W. Houston pers. comm.). The horns start growing at ca. 9 months, reach ear length and about one complete twist at 1.5 years and are fully developed at 4–5 years (cf. Fig. 27 in Leuthold, W. 1979). Little is known on life-span; some wild animals in Tsavo N. P. attained at least 8–10 years (Leuthold 1979b), captive animals 14–19 years (Váhala 1992, Weigl 2005).

Because of the problems in counting the animals accurately, data on population structure are difficult to evaluate. In Tsavo N. P., adult ♂♂ comprised ca. 10–15% of the sample, and the sex ratio among animals over one year old varied between 1 : 1 and 1 : 2. There were ca. 0.3 juveniles (<1 year) per adult ♀. Other data suggested a rather high mortality of juveniles, with ca. 50% of newborn animals dying within their first six months. It thus appears that natality may be near its potential maximum and that the population is regulated mainly through mortality.

Predators, Parasites and Diseases Adult animals probably fall prey only to the largest predators, i.e. Lions *Panthera leo*, Leopards *P. pardus*, Spotted Hyenas *Crocuta crocuta* and African Wild Dogs *Lycaon pictus*, but there are no data on quantitative aspects of predation. Young animals may also be killed by smaller predators, including large birds of prey (e.g. Martial Eagle *Polemaetus bellicosus*), and possibly baboons *Papio* spp. (Leuthold, W. 1979).

Not much is known on parasites or diseases, except that the Lesser Kudu is highly susceptible to rinderpest (e.g. Stewart & Stewart 1963). Considerable mortality has occurred repeatedly during periodic outbreaks of this disease, most recently in and near Tsavo N. P. in 1994/95 (Kock 1997, East 1999, S. Kasiki pers. comm.). Cleaveland *et al.* (2005) reported infection of bovine tuberculosis, caused by *Mycobacterium bovis* from one Lesser Kudu killed by sport hunters adjacent to Tarangire N. P.

Conservation IUCN Category: Near Threatened. CITES: not listed.

The semi-arid nature of the Lesser Kudu's habitat precludes intensive utilization of the land by man for agricultural purposes. However, pastoralism and other forms of land use, for example collection of firewood, have increased in recent years and this trend is likely to continue with expanding human populations. Political unrest and wars have been prevalent in much of the species' range, which has a three-fold effect. (1) The number of firearms available and thus illegal hunting pressure (meat hunting and/or trophy hunting for skins or horns) may increase; Funaioli & Simonetta (1966) mention up to 20,000 skins having been sold in a single year in Somalia, with an average of 11,000 per year between 1952 and 1963, almost all as a result of poaching. (2) Supervision of the areas concerned, even protected ones, and law enforcement become more difficult and may cease entirely for certain periods of time. (3) All this also makes it more difficult to conduct surveys and to obtain reliable information on the status of wildlife.

The Lesser Kudu is reported to be fairly common outside protected areas in Ethiopia and Somalia, even though its numbers have probably decreased markedly in recent years (M. J. Jacobs & C. A. Schloeder

pers. comm., T. L. Thurow pers. comm., F. Wilhelmi pers. comm.). On the other hand, considerable areas within the species' range are under some kind of legal protection, such as Ruaha N. P. and surrounding game reserves, Tarangire N. P. and Mkomazi G. R. (Tanzania), Tsavo and Meru National Parks (Kenya), Awash, Omo and Mago National Parks (Ethiopia) and Bushbush N. P. (Somalia), in addition to a number of Game Reserves. East (1999) estimates that roughly one-third of the Lesser Kudu populations occur in protected areas.

Overall, the Lesser Kudu is not immediately threatened, but its numbers are likely to decrease further, while its range will become more and more fragmented. Measures to be taken include ensuring the integrity of protected areas, adequate law enforcement elsewhere, and possibly efforts to contain rinderpest.

Measurements

Tragelaphus imberbis

HB (♂♂): 1600–1750 mm*

HB (♀♀): 1100–1300 mm

T (♂♂): 300–400 mm

T (♀♀): 250–300 mm

Sh. ht (♂♂): 1000–1100 mm*

Sh. ht (♀♀): 900–1000 mm*

WT (♂♂): 95–105 kg

WT (♀♀): 80–95 kg

Throughout geographic range (Haltenorth & Diller 1980, *Kingdon 1997)

Ledger (1964) recorded average weight for 10 ♂♂ from Tsavo N. P. at 92.1 kg (range 56–108), though this probably included some subadult ♂♂

Record horn length is 83.5 cm for a pair of horns from the Omo Valley, Ethiopia (Rowland Ward)

Tragelaphus angasii NYALA

Fr. Nyala; Ger. Tiefland-Nyala

Tragelaphus angasii Angas, 1849. Proc. Zool. Soc. Lond. 1848: 89 [1849]. South Africa, KwaZulu–Natal, ‘Hills that border upon the northern shores of St. Lucia Bay, in the Zulu country, lat. 28° south’. [Attribution to Angas, 1849, and not Gray, follows Grubb 2004, 2005].

TOP: Adult male Nyala *Tragelaphus angasii*; MIDDLE: Adult female Nyala *Tragelaphus angasii*; BOTTOM: Subadult Nyala *Tragelaphus angasii*.

Taxonomy There are no recognized subspecies. Genetic variation, on the basis of microsatellite, mitochondrial control region and allozyme markers, occurs between the Malawi, Mozambique and KwaZulu–Natal populations and it is postulated that this geographic variation is a function of a distribution pattern stemming from habitat specificity (Grobler *et al.* 2005). Synonyms: none. Chromosome number: $2n = 55$ for ♂ and $2n = 56$ for ♀ (Wurster & Benirschke 1968, Wallace 1980).

Description No other antelope shows such extreme sexual dimorphism as the Nyala, with adult ♂♂ almost twice the size of ♀♀ (Anderson 1976). Females, and young of both sexes, are russet brown, with up to 18 vertical white stripes running from shoulders to hindquarters. At one year of age general coat colour of ♂♂ is still same as ♀♀, but hair on neck has darkened while that on throat, sides of belly and dorsal ridge has grown noticeably longer than in ♀♀. Change in coat colour and length occurs rapidly between 14 and 16 months of age, the age at which spermatogenesis begins. This is accompanied by rapid increases in testis weight and seminiferous tubule diameter. Adult ♂♂ are predominantly charcoal grey; lower legs remain russet brown, stripes and spots are retained and animals develop a white chevron on top of the muzzle. Up to three white spots on the cheeks and white spots on the upper hindleg. Bases of backs of ears white. Dorsal crest of long hair (dark on neck), and a heavy fringe of long hair (slightly darker than hair on body) on underparts of the neck to the belly. Long hair on tail dark, but underside white; this is very obvious in the male dominance ritual. In older individuals the stripes are reduced to three or four, or are absent entirely. Very rarely adult ♂♂ occur that have retained their juvenile pelage (those that have been examined exhibited either cryptorchidism or had undeveloped testes). Adult ♀♀ may or may not have a white chevron present between the eyes, also have a dorsal crest (though they lack the fringe of hairs on the throat and belly) and the lower parts of the legs do not contrast with the overall body colouration as is the case in ♂♂. Both sexes have glands at the base of the false hooves, but inguinal and preorbital glands are absent. Females have two pairs of inguinal nipples.

Aberrant-coloured Nyalas have been recorded. Dixon (1964) reported a ♂ from Mkuzi G. R., KwaZulu–Natal, which was pale beige in colour, and Lobão Tello & Van Gelder (1975) recorded a pale yellowish-coloured ♀ and a palomino-coloured ♂ from Zinave N. P. in Mozambique.

Only ♂♂ have horns, which are keeled and grow in a shallow spiral. Horns first develop between five and six months (Anderson 1986). In adult ♂♂ the tips of the horns are whitish partly as a result of the frequent ‘horning’ of moist earth when animals visit a waterhole. Age determination is discussed by Anderson (1986): adult dentition is attained at two years by which time the horns are half-grown (reaching mature size at 4.5 years).

Tragelaphus angasii

Geographic Variation None recorded, but see Taxonomy.

Similar Species

Tragelaphus spekii. Not sympatric. Similar in body size, but less strikingly marked and has typically elongated hooves as an adaptation to its swamp habitat. The male's horns are very similar in size and shape to those of the Nyala.

T. scriptus. Sympatric throughout the range of the Nyala. Smaller, and without long hair on the underside of adult ♂♂; comparatively straighter and shorter horns and more dependent on closed habitats and a dicotyledonous diet. A similar though less pronounced sexually dimorphic colour change is shown, particularly in the southern subspecies *T. s. sylvaticus*.

Distribution Endemic to Africa. Inhabits dense thickets and open thicket woodland mosaics in Malawi, Mozambique, Zimbabwe, South Africa and Swaziland.

Historical Distribution Originally confined to the hot, low-altitude areas of south-eastern Africa, below the 18° isotherm. North of the Zambezi R., found only in the Lower Shire valley in Malawi (Sidney 1965, Ansell 1981). South of the Zambezi R., Nyalas were widespread in Mozambique and occurred as far south as the Hluhluwe R. (about 28° 20'S) in KwaZulu–Natal, South Africa. In Zimbabwe, NE South Africa (KwaZulu–Natal) and NE Swaziland they were found in scattered pockets in suitable habitats, mainly along the major river valleys. In South Africa, Rautenbach (1982) remarks that Nyala occurred naturally as far west as Ellisras in what is now Limpopo Province. Nyalas suffered severe mortality during the 1895/96 rinderpest epizootic and this may account for the discontinuous distribution and low numbers encountered at the end of the nineteenth century (Selous 1909).

Current Distribution Currently more widespread, because since the early 1960s animals have been translocated from game reserves in

Lateral view of skull of Nyala *Tragelaphus angasii*.

KwaZulu–Natal to other protected areas and private ranches in areas both within and outside of their former distribution range (including even the farming districts in N Namibia). Where habitats are suitable and the areas selected do not experience cold wet winters, the species has adapted well to artificial dispersion. Animals from NW South Africa have spread into neighbouring parts of Botswana, such as the Tuli Block.

Habitat Thicket and forest are essential habitat requirements for Nyalas. They use these when resting during the heat of the day and seek shelter in them during cold and inclement weather. When alarmed, Nyalas always escape to the nearest cover. At least 10% of the home-ranges of animals studied in Hluhluwe G. R. consisted of forest (Anderson 1976) and, in Mozambique, Lobão Tello & Van Gelder (1975) showed that in one year 90% of Nyalas observed were in association with thickets. They frequent both flat and hilly landscapes, naturally occurring up to an altitude of about 400 m, and, although it is not essential, prefer to be in the vicinity of permanent water. At night, Nyalas use open habitats more readily than in daylight, but they are seldom far from cover. In the dry season they regularly use the river flood-plains in Ndumo G. R. in KwaZulu–Natal.

Abundance The demand for Nyalas on private ranches has increased their distribution and numbers in South Africa, Swaziland and Zimbabwe, and also in Namibia, where the species has never occurred naturally. East (1999) estimated the total population of Nyalas to exceed around 32,000 individuals. However, more recent estimates suggest South Africa has at least 30,000 (a slight increase from the estimate of East [1999]), with the largest populations (25,000) in KwaZulu–Natal (P. Thomson pers. comm.). The major populations are in the Game Reserves of Ndumo (4000), Mkhuze (7000) and Hluhluwe–iMfolozi (7000) (Rowe-Rowe 1994). Kruger N. P. and adjoining game reserves have in excess of 3000 animals.

In Swaziland, the species was extinct by the 1950s, but they have been successfully reintroduced (and introduced to other parts of the country) and there are now more than 1000 on protected areas and ranches (Monadjem 1998). Nyalas are still widespread in Mozambique but, because of uncontrolled hunting, at very low densities and numbers probably do not exceed 3000 (J. Anderson, pers. obs.). Zimbabwe has more than 1000, the majority in Gonarezhou N. P. and on game ranches in the south-east. Numbers in Malawi have declined from 3000 (East 1999) to about 1500, most notably in the population in Lengwe N. P. (which was originally created especially for this species) and in Mwabvi G. R. where a relict population is thought still to occur (S. Munthali pers. comm.). There are about 350 in two populations on private property. Extralimital to the species' natural range, Namibia has about 250, all on private ranches.

Adaptations The conspicuousness of the dominance display (see below) between Nyala ♂♂ is accentuated by the long fringe of hair on each side of the belly and hindlegs and the erectile ridge of white hair running along the spine. These increase the visual surface area presented in the lateral display by up to 40%. Furthermore, the body appears to be laterally compressed, in cross-section being more elliptical than oval. The torso of a Nyala ♂ is 67% of its lateral silhouette, whereas that of an Impala *Aepyceros melampus* ♂, which does not have a lateral display, is only 58% (Anderson 1976).

Although adult ♂♂ are twice the weight of ♀♀, their molariform toothrows are the same length. The need to eat more than ♀♀ may influence a greater rate of tooth wear in ♂♂. At the end of the dry season, this has implications for physical condition and related mortality (Anderson 1976). The morphology of the stomach is similar to that of intermediate feeders (Hofmann 1973). The rumen papillae are not as 'leaf-like' as those tragelaphines that are concentrate selectors, but more closely resemble those of 'browsing' Impala (Hofmann 1973).

Foraging and Food Nyalas are intermediate feeders or generalists that feed selectively on both the leaves and fruits of woody plants as well as grasses (Hofmann 1973, Gagnon & Chew 2000), and this is borne out also by studies involving stable carbon isotopes (in which their diet was estimated to contain approximately 33% grass; Sponheimer *et al.* 2003b). The proportions of these components change in relation to their seasonal availability (Anderson 1976, Van Rooyen 1992). In Ndumo G. R., grasses formed the bulk of the diet during the rainy summer months and, as these dried out in winter, the proportion of browse eaten increased. Munthali (1991) found that in Lengwe N. P. in Malawi, Nyalas were primarily browsers but increased their intake of grasses over the wet season.

The most important grasses were those that grew under shade such as *Panicum maximum* and *Dactyloctenium australe*. The most commonly recorded woody plants eaten in Ndumo G. R. were *Trichelia emetica*, *Spirostachys africana*, *Sclerocarya birrea*, *Maytenus heterophylla*, *Gardenia cornuta* and *Ziziphus mucronata* (Anderson & Pooley 1977). In Lengwe N. P., the most important browse plant was *Salvadora persica* (Munthali 1991). Lobão Tello & Van Gelder (1975) recorded 108 species of browse plants utilized by Nyalas in Mozambique, with the Mustard Tree *Salvadora persica* particularly heavily utilized. The incidence of fruits and flowers in the diet is seasonal. In some areas animals venture onto open grasslands or flood-plains at night to feed on green grasses and forbs.

Although Nyalas drink daily where water is available, in parts of their range in Mozambique and Zimbabwe they are found where no surface water is present for several months of the year (Davison 1971, Lobão Tello & Van Gelder 1975).

Social and Reproductive Behaviour The social organization is based on the female unit, consisting of an adult ♀ and her offspring of varying ages (Anderson 1980). The typical female herd size (5.6) is formed by the association of two or more ♀♀ and their young. This association is not entirely random and there is a positive association between related female units. Loose temporary aggregations of up to 30 animals occur at water points.

Males leave the female unit of their own accord at between 14 and 24 months and begin to associate with other ♂♂, particularly those of similar age. The typical male group size is 2.7, but these are

not cohesive and seldom last for more than a day. With increasing age and body size, ♂♂ become more dominant and progressively more solitary, probably because of avoidance by younger ♂♂.

Nyalas are not territorial, and both sexes have overlapping home-ranges of approximately equal size; these appear to be inversely correlated with food availability. In Zinave N. P., the average home-range of adult ♂♂ was 5.5 km² (Lobão Tello & Van Gelder 1975) whereas in the more mesic Hluhluwe G. R. both ♂♂ and ♀♀ had home-ranges of about 1 km² (Anderson 1980). Home-range size may increase during the dry season in relation to the distribution of surface water. There is no marking, but adult ♂♂ frequently horn moist ground at water points and occasionally 'weave' and thrash bushes. These offensive threats often take place in isolation and are not directed towards other ♂♂.

Sire selection is achieved by temporary dominance asserted in the presence of an oestrous ♀. Dominance is achieved by a striking ritual where the main feature is a slow and deliberate lateral display with lowered head, raised dorsal ridge, and tail arched over the hindquarters with the long white hairs fanned out. Body size, and those physical features that serve to accentuate this, usually decide the outcome of the display. Young ♂♂ spar with one another, but this becomes less frequent with age. Occasionally, there is a clash of horns in the presence of an oestrous ♀. Fighting is very rare, but when it does occur is fierce and can often result in severe injuries or deaths (Anderson 1980).

When a ♂ encounters a ♀, he will test her for oestrus by smelling at the base of her tail. Males tested ♀♀ and performed flehmen in 127 of 130 male–female encounters recorded (Anderson 1976). Males only show strong flehmen in response to oestrous ♀♀. Overt oestrus lasts for about two days, during which more dominant animals may progressively replace each consorting ♂. The ♀ permits copulation for a period of about six hours, towards the end of overt oestrus when mating takes place repeatedly. The female unit is disrupted during this period and this generally accounts for sightings of lone juvenile animals.

Birth usually occurs in cover, rarely in the open (Lobão Tello & Van Gelder 1975). It is assumed that the ♀ leaves the group at this time. After giving birth, the ♀ cleans the newborn calf and eats the placenta and placental membranes. The calf lies up for about 18 days (Anderson 1980) until strong enough to accompany its mother. Female calves remain with their mothers until they in turn have their own first calf.

Nyalas are usually silent, but they do emit an alarm call, akin to a dog-like bark (and somewhat similar to that of Bushbucks *Tragelaphus scriptus* and Greater Kudus *T. strepsiceros*), which results in other animals nearby taking flight. Animals bleat when in distress and ♀♀ make a soft throaty clicking when in oestrus or tending a young calf.

In suitable habitats, Nyalas may be found feeding in association with Bushbucks, Impalas and Chacma Baboons *Papio ursinus*. Nyalas show no concern for baboons in these circumstances, and this is when adult male baboons occasionally prey on young Nyalas. Dean & MacDonald (1981) recorded an instance of a Chorister Robin-chat *Cossypha dichroa* gleaning a Nyala.

Reproduction and Population Structure Spermatogenesis starts at about 12 months and by 14 months of age all ♂♂ show active spermatogenesis. However, in a wild population, ♂♂ may only

breed when they are around five years old (Anderson 1984). There is no seasonal sexual cycle in ♂♂ (Anderson 1984). Ovulation first occurs between 14 and 18 months of age. By 20 months, 50% of the ♀♀ sampled from Ndumo G. R. were sexually mature. In captivity, ♀♀ as young as 11 months have conceived, presumably because of a high plane of nutrition. Between sexual maturity and senescence, at about 14 years of age, ♀♀ are either pregnant or at some stage of the oestrous cycle (i.e. anoestrus does not occur).

Implantation is homolateral and the gestation period is about 220 days. A single calf is the norm; twin foetuses were recorded only once in 217 conceptions examined in KwaZulu–Natal (Anderson 1984). The average weight of two newborn young was 5.6 kg. The shortest parturition interval recorded was 231 days, though the average parturition interval in Ndumo G. R. was 297 days. The interval between overt oestrous cycles ranges between 10 and 34 days. There is a postpartum oestrus that occurs between two and seven days after parturition. The ♀ will continue to come into oestrus until she conceives again. Lactation lasts about seven months (Anderson 1984).

Conceptions occur throughout the year in the wild (and in captivity, see Skinner *et al.* 2002), but there are two peaks, one in autumn and the other in spring. It is possible that these peaks are initiated by two, as yet undetermined, light or photoperiod cues. The absence of strong environmental feedback does not reinforce these cues enough to make the peaks very obvious or allow one to become dominant. They are further obscured by the seven-month gestation period and individual differences in the age of sexual maturity, oestrous cycles and duration of the parturition intervals (Anderson 1979).

There is an even sex ratio at birth and up to the age of a year (Anderson 1976). Males made up 45% of the adult population in an undisturbed population in Hluhluwe. Over a period of six years, the proportion of ♂♂ ranged from 32% to 64% of the adult segment of the population in Ndumo G. R. The percentage of immature animals recorded in various populations was 31% (Zinave N. P.), 32% (Hluhluwe) and 43% (False Bay Park). The different sex ratios between populations, and within the same population over time, can be ascribed to differences in habitat, predation pressure and management regime.

Seasonal changes in condition of Nyalas in Ndumo G. R. were measured and correlated with the rainfall of the previous month. Following periods of less than 50 mm rainfall per month (Anderson 1985), adult ♂♂ were in significantly lower condition than other sex/age classes. This was attributed to the fact that adult ♂♂ required 62% more kcal/day than adult ♀♀, yet had the same size jaw and tooththrow as ♀♀.

There is an increase in mortality towards the end of the dry season. Sporadic die-offs in protected areas in KwaZulu–Natal occur when unseasonable rain falls in the winter or early spring and is accompanied by a cold wind (Keep 1973, Anderson 1985). In 'die-offs' due to nutritional stress, significantly more young adults survived and significantly more adult ♂♂ died than would be expected to occur at random. Also, significantly more ♂♂ died than ♀♀ (Anderson 1985). Munthali (1993) recorded similar 'die-offs' in Lengwe N. P., and also noted that adult ♂♂ regained body condition slower than ♀♀.

Life tables from Ndumo G. R. showed that ♂♂ very rarely lived beyond 12 years of age and ♀♀ seldom beyond 14. There was also

a 34% mortality of calves within the first six months (Anderson 1976). Jones (1993) gives a longevity record in captivity of 15 years and 10 months.

Predators, Parasites and Diseases Nyalas are preyed upon by all the larger African carnivores that share their range and also by Nile Crocodiles *Crocodylus niloticus* and African Rock Pythons *Python sebae*. In Hluhluwe-iMfolozi Park, Lions *Panthera leo* account for the majority of kills. Young animals frequently fall prey to adult male baboons and occasionally to larger eagles.

No diseases have been found responsible for Nyala deaths in southern Africa in recent years. However, many Nyalas died as a result of the rinderpest epizootic that swept through Africa in 1895 and 1896.

Keep (1971) collected ten species of ticks and 13 species of helminth parasites from Nyalas in KwaZulu–Natal game reserves. He also recorded *Theileria*-like piroplasms and *Trypanosoma ingens*-like parasites in the blood (and see Bigalke *et al.* 1972). He found a high incidence of endarteritis caused by the filarial parasite *Cordophilus sagittus* in the lungs of Nyalas in Ndumo G. R. and *Cordophilus* cysts in 22% of a sample from the coronary vessels of outwardly healthy animals. In Mkhuzi G. R., Boomker *et al.* (1996) recorded helminths from a sample of 64 Nyalas, and amended the list of helminth parasites recorded from Nyalas to 30 species (see Boomker *et al.* 1991a), including five trematodes, three cestodes and 22 nematodes; *Camelostrongylus harrisi* and *Camelostrongylus* sp. were the most numerous and prevalent of the nematode burden. They concluded that the faecal egg counts could not be used to determine the nematode populations in antelope in the reserve, and also found that the magnitude of the total burdens was insignificant and in no way detrimental to Nyalas.

In iMfolozi, Mkhuzi and Ndumo Reserves, Horak *et al.* (1995a) recorded ten ixodid tick species, two louse species (*Damalinea* sp. and *Linognathus angasi*) and a louse fly (*Lipoptena paradoxa*); the most abundant tick species on Nyalas were *Rhipicephalus muelhensi* (and see also Horak *et al.* 1983c), *Rhipicephalus appendiculatus* and *Boophilus decoloratus*, the former two species preferring the ears, heads and upper necks of male Nyalas as attachment sites. The Nyala is the host to the wingless hippoboscid fly *Echestyphus pardoxus*, which is not known to cause any skin damage or carry any infectious disease (Keep 1971).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although Nyalas have disappeared from some parts of their former range, and have undergone some declines even in protected areas (such as Lengwe N. P.), they continue to survive in good numbers in a number of effectively managed protected areas (in particular the reserves of Ndumo, Mkhuzi and Hluhluwe-iMfolozi in KwaZulu–Natal, and in Kruger N. P.) and on private land, both within and outside their natural range. Currently, more than 80% of the Nyala population in South Africa occurs in protected areas (East 1999). The dispersion of Nyalas and their increase in numbers in South Africa is due primarily to the high demand for adult ♂♂ by trophy hunters. Efforts to rehabilitate the protected areas network of Mozambique (in particular Gorongosa, Banhine and Zinave National Parks) will be beneficial for the species.

In the absence of natural predation or population management, there have been several instances where Nyalas have increased to the detriment of Bushbuck and Suni *Nesotragus moschatus* populations. This is probably because, where the three species occupy the same habitat, Bushbucks and Sunis are almost exclusively browsers, but Nyalas being mixed feeders with a greater browse height have a competitive advantage in the late dry season when available browse is limited. Seymour (2002) found that where Nyalas, Bushbucks and Greater Kudus occurred together, there was little overlap with Bushbucks during the wet season as Nyalas selected slightly more open habitats and fed primarily on grass. During the dry season there was a high degree of overlap between Nyalas and Bushbucks in both diet and habitat use.

Measurements

Tragelaphus angasi

HB (♂ ♂): 1676 (1590–1980) mm, n = 20

HB (♀ ♀): 1432 (1323–1463) mm, n = 19

T (♂ ♂): 427 (370–470) mm, n = 22

T (♀ ♀): 360 (342–399) mm, n = 10

HF c.u. (♂ ♂): 474 (425–557) mm, n = 21

HF c.u. (♀ ♀): 422 (402–443) mm, n = 11

Sh. ht (♂ ♂): 1121 (1040–1210) mm, n = 17

Sh. ht (♀ ♀): 966 (825–1060) mm, n = 8

WT (♂ ♂): 107.5 (92.5–126.5) kg, n = 13

WT (♀ ♀): 61.8 (54.9–68.1) kg, n = 8

Zinave N. P., Mozambique (Lobão Tello & Van Gelder 1975)

Maximum recorded horn length is 83.5 cm for a pair of horns from KwaZulu–Natal, South Africa (Rowland Ward)

Tragelaphus strepsiceros GREATER KUDU

Fr. Grand Koudou; Ger. Grosskudu

Tragelaphus strepsiceros (Pallas, 1766). Misc. Zool. p. 9. 'Prom. B. Spei' (Cape of Good Hope); restricted to South Africa, south-eastern Cape Prov. (= eastern part of Western Cape Prov.) by Grubb (1999: 36).

Taxonomy Originally classified simply as an 'antelope', the Greater Kudu was assigned by Blainville to the genus *Tragelaphus* in 1816. Ansell (1972) distinguished four subspecies on the basis of stripe patterns: *T. s. bea*, from Tanzania, N Mozambique and Kenya; *T. s. chora*, from Somalia, Ethiopia and E Sudan; *T. s. burlacei*, from Chad and Central African Republic, and possibly W Sudan; and the nominate form, from Zambia, Malawi southwards. Kingdon (1997) recognized three subspecies: *T. s. strepsiceros* (East Africa and South Africa), *T. s. chora* (north-east Africa) and *T. s. cottoni* (Chad, W Sudan), although the latter name is not available. Both Ansell (1972) and Haltenorth (1963) cautioned that since the stripes are so variable, the basis for subspecific recognition is dubious. An isolated naturally occurring population in South Africa's Eastern Cape Province has been regarded as a separate subspecies. Mitochondrial DNA markers suggest a substantial differentiation of the south-west African lineage from those elsewhere in Africa, although morphological differences are not apparent (Nersting & Arctander 2001). A single sample from N Kenya suggests that this population is genetically distinct, supporting the subspecies differentiation as *T. s. chora*, but confirmation from a larger sample is needed. The combined analysis of individual lineages, relationships and population genetics suggests a colonization process from southern Africa towards East African regions. Synonyms: *abyssinicus*, *bea*, *burlacei*, *capensis*, *chora*, *cottoni*, *excelsus*, *frommi*, *hamiltoni*, *koodoo*, *torticornis*, *typicus*, *zambesiensis*. Chromosome number: 2n = 31 for ♂ and 2n = 32 for ♀ (Gallagher & Womack 1992). There are two well-documented records of hybrid male offspring between a Greater Kudu and Common Eland *Tragelaphus oryx*, one known to be sterile, the other unknown (Jorge *et al.* 1976, Van Gelder 1977a).

Description Large majestic antelope characterized by striped body, humped shoulder region, long neck and huge spiral horns carried by ♂ ♂, which are also much larger in body size than ♀ ♀. Head markings include a V-shaped white bar on the forehead between the eyes, white

Greater Kudu *Tragelaphus strepsiceros*.

Greater Kudu *Tragelaphus strepsiceros* in strutting posture.

lips and chin, and one to four spots on the cheek. Ears are large and rounded, pinky-brown on the interior with tufts of white hairs near the base and white margins. Body colour varies from fawn or cinnamon to grey-brown, lower legs more tawny than the body with dark mark on inner knee and black band above hooves. White stripes on the body are variable in number, spacing and boldness, with 3–9 in the flank region and 2–5 on the hindquarters. Some stripes may be forked, and some animals show spots or bars between the stripes. Stripes tend to fade with age. Both sexes have a dorsal fringe of hairs extending from the neck along the back to the tail base, commonly white-tipped, with a prominent crest of hairs on the shoulders. Males also bear a long mane from the throat along the underside of the neck almost to the chest, commonly showing a dark middle band, plus a fringe of short dark hairs on the belly. Tail broadly fluffy with long hairs, white on the underside with a dark brown tip. Interdigital glands are present. Testes are quite small compared with most other antelopes, their combined weight only 0.04% of body mass even during the peak mating period (Skinner & Huntley 1971). The Nyala *Tragelaphus angasii* is similar in this respect (Anderson 1984), while in the Bushbuck *T. scriptus* the testes are relatively about twice as large (Allen-Rowlandson 1986). Necks of mature ♂♂ bulge markedly during mating season. Females have two pairs of inguinal nipples.

Horns of fully adult ♂♂ complete two full spirals with the tips extending forwards or even outwards and back, with a prominent ridge following the curvature. Females are hornless, although horned ♀♀ are occasionally recorded. Males can be placed into age categories by the direction of the spiralling horn tips. Three-year-olds have the horn tips pointing back and out, four-year-olds have the horn tips directed back and inwards, and five-year-olds have the tips curving forwards. By six years, both tips point forwards.

Lateral view of skull of Greater Kudu *Tragelaphus strepsiceros* female.

However, there is individual variation related to how narrow or wide the span is between the horn tips (N. Owen-Smith pers. obs.; see also Simpson 1971, 1972b). Patterns of tooth eruption are described by Simpson (1966), who demonstrated that ♂♂ could be aged up to about eight years by counting the cementum layers in the teeth, and relating these to the 'cheeks' or transverse ridging on the horns caused by seasonal fluctuations in growth.

Geographic Variation Individuals vary quite widely in their stripe patterns, but without any clear geographical variation. Ansell (1972) suggested a pattern of clinal variation from darker colour, more stripes and longer horns, in the south, to paler colour, fewer stripes and shorter horns in the north.

Similar Species

Tragelaphus imberbis. Sympatric in northern parts of the range. Similar in basic appearance and spiral horns (though not having the same spread), but attains less than half the body mass. Adult ♂♂ lack the dense fringe of hair along underside of neck. White patch at base of neck.

T. buxtoni. Ethiopian Highlands only, potentially sympatric in some mountain slopes. Similar in size and body colour, but has less distinct stripes and shorter horns with fewer spirals.

T. eurycerus. Allopatric. Somewhat heavier with numerous bright stripes against a dark chestnut-brown background.

Distribution Endemic to Africa.

Historical Distribution In South Africa, formerly occurred in the Northern Cape, NE KwaZulu–Natal and the North West, Limpopo, Mpumalanga and Gauteng Provinces, with an isolated population in the Eastern Cape, and scattered populations in the Free State. From South Africa the species ranged widely through Namibia (excluding the drier coastal parts), Botswana, Zimbabwe, S and C Angola, Zambia (absent from the wetter savanna woodlands of the northern plateaux), Mozambique, Malawi, SE DR Congo, to Tanzania and Kenya (East 1999). Somewhat rare and localized in occurrence (often in hilly areas) north of the equator, from Kenya and east Karamoja in E Uganda through the Rift Valley and western, eastern and southern lowlands of Ethiopia, W Eritrea, S Djibouti, Somalia, W and SE Sudan (and along the Ethiopia/Eritrea borders), S and SE Chad and N Central African Republic (north of the Ouandja and Koumbal Rivers) (East 1999). Naturally absent from the Serengeti region of N Tanzania and adjoining plateau region of S Kenya.

Current Distribution Greater Kudus have remained common through most of their southern range, even on ranching land and close to settlements, and have extended their distribution westwards in

parts of southern Africa, such as the Karoo and Kalahari. Only in SE DR Congo is their status unclear, although they survive at least in Kundelungu N. P. (East 1999). To the north, the species may now be extinct in Djibouti, where a few were reported to survive in the south on the Ethiopia border in the mid- to late-1980s (East 1999, Heckel & Rayaleh 2008). In Somalia, Simonetta (1988) suggested they may survive on the northern slopes of the Gaan Libah in the north-west, while East (1999) considered them extinct; recently discovered museum records of specimens collected in the 1960s from S and C Somalia that expand the known historical range suggest this may be premature (Gippoliti & Fagotto in press). There is no recent information on their status in Sudan (they were not recorded during recent surveys in the south; Fay *et al.* 2007) or Uganda (East 1999).

Habitat Greater Kudus occupy a wide range of savanna vegetation types, from dry thornbush with rainfall as low as 200 mm through to mixed broad-leaf woodlands with rainfall approaching 1000 mm. Most widely abundant in drier savanna regions where they are commonly associated with rocky hillslopes, and especially common in succulent thickets or 'valley bushveld' where there is a high evergreen component including the leaf-succulent Spekboom *Portulacaria afra*. Absent from closed forests and treeless grassland, but may forage into quite open parkland where denser woody vegetation adjoining hillslopes or water-courses occurs nearby. They occur in arid shrubland and semi-desert along riparian corridors. Absent from extensive areas of Umbrella Thorn *Acacia tortilis* savanna where a dry season reserve of evergreen or semi-evergreen browse is lacking. Males concentrate more in riparian woodland and thicket along drainage-lines than female herds (du Toit 1995), although ♀♀ shift their feeding towards river-lines during the dry season (Simpson & Cowie 1967). Greater Kudus have been recorded to elevations of 2400 m in Ethiopia (Yalden *et al.* 1996).

Abundance Densities in savanna woodland reach 2–3/km² locally (Owen-Smith 1990), but can exceed 10/km² in succulent

thickets of the Eastern Cape (Allen-Rowlandson 1980). Population densities obtained from aerial counts are generally less than 0.5/km² even in areas where the species is reasonably common (see East 1999), but may underestimate the true population by a factor of two. East (1999) estimated a total population of around 482,000 Greater Kudus, with the largest populations found in Namibia (more than 200,000), where the species remains widely abundant on private farmland, and South Africa (more than 60,000).

Adaptations The trophic morphology and anatomy of the Greater Kudu is fairly typical of a browser, but with physiology deviating from that of small concentrate selectors like duikers. The muzzle and incisor toothrow are relatively narrow, and the premolars and molars have prominent cusps adapted for puncture-crushing of dicotyledonous foliage. The reticulum has a heavily keratinized lining apparently protective against thorns and woody stems ingested. The capacity of the rumen plus reticulum is moderate, about 27 litres in adult ♀♀ and 58–71 litres in adult ♂♂ (Hofmann 1973). The rumen is generally filled to no more than 60% of capacity with solid material, presumably to accommodate gases released from rapidly fermenting forage. The wet mass of rumen contents averages 11% of body mass, or 1.8% as dry mass ranging from 1.55% in the wet season to 2.1% in the dry season (Giesecke & Van Gylswyk 1975, Boomker 1987). This is somewhat smaller than in grazing ruminants. Fermentation rate of rumen contents is substantially lower than in small browsers, and a fairly high proportion of acetic to propionic acid is produced, indicative of substantial fibre digestion. The absorptive surface of the rumen mucosa is greatly enlarged by dense papillae. The omasum is well developed with laminae increasing the absorptive surface for water and electrolytes. Parotid salivary gland quite small, about 0.06% of body mass (Robbins *et al.* 1995), in contrast to Giraffe *Giraffa camelopardalis* and most other browsers. This suggests that detoxification via the liver is more important than salivary deactivation of tannins.

Greater Kudus have a fairly sparse pelage, enabling them to be active despite temperatures as high as 36°C during summer, but develop a more shaggy coat during the South African winter (Owen-Smith 1998). They can exist for long periods without drinking, obtaining sufficient moisture from their food (du Toit 1995), but become water dependent at times when the vegetation is very dry. In semi-desert areas of Namibia and the Kalahari they satisfy their moisture requirements by consuming Tsama Melons *Citrullus lanatus*. Drinking usually takes place during the late morning.

Greater Kudus are renowned jumpers, with adult ♂♂ able to clear fences 2 m in height from a standing position. While running through thick vegetation ♂♂ hold their noses forwards so that the long horns are extended over the back. Vision, hearing and sense of smell are all good, and they are difficult to approach closely in the dense vegetation they usually inhabit. While moving through open habitats they are cautious and tend to follow corridors of denser vegetation.

Greater Kudus are active nocturnally as well as during daylight, and the species is a common cause of road accidents along highways at night. The main foraging periods are during the morning, and from the late afternoon into the night, plus commonly a brief foraging spell around midday during the hottest time of the day. On average about 63% of daylight and 48% of the night is devoted to foraging. Activity levels are highest during the dry–wet season transition when

high-quality food becomes available in small amounts, and lowest over the late wet season when food is most abundant (Owen-Smith 1998). A sleeping spell occurs in the pre-dawn period, when animals lie curled with the head laid on the flank.

Foraging and Food Greater Kudus are browsers, as evidenced both by direct observations and dietary studies involving stable carbon isotope analysis (Cerling *et al.* 2003, Sponheimer *et al.* 2003b). They have an exceptionally broad diet, both in terms of plant species eaten as well as food types. Almost 150 species of plants were recorded as eaten in Kruger N. P., South Africa (Brynard & Pienaar 1960), while in Nylsvley N. R. in the Limpopo Province of South Africa they consumed on average 40 species per day (maximum 59), subdivided equally between forbs and woody plants (Owen-Smith 1994). Deciduous woody plants form the staple dietary component for most of the year, especially various mimosa thorn-trees (*Acacia* spp.), bush-willows (*Combretum* spp.) and raisin-bush (*Grewia* spp.) (Owen-Smith 1979, 1994, Novellie 1983, Owen-Smith & Cooper 1989). In Zambia, other woody species commonly browsed include *Diplorhynchus condylocarpon*, *Pseudolachnostylis maprouneifolia*, *Trichilia roka*, *Bauhinia petersiana* and *Albizia harveyi* (Wilson 1965). However, forbs are especially favoured, particularly soft-stemmed creepers, annuals and perennials like *Justicia* and *Commelina* spp., and form 40–60% of the wet-season diet in Kruger N. P. and Nylsvley N. R. Certain fruits are sought out when available, notably the pods of certain *Acacia* spp., *Dichrostachys cinerea* and *Piliostigma thonningii*, succulent drupes of marula *Sclerocarya birrea* and *Ximenia caffra*, large hard-shelled monkey-oranges (*Strychnos* spp.), kudu-berries (*P. maprouneifolia*), goat apples (*Solanum* spp.) and wild cucumbers (*Cucumis* spp.).

During the dry season the diet is widened to include the foliage of less palatable woody species, notably certain evergreens, including Monkey-orange (*Strychnos pungens*) and Mountain Karee *Rhus leptodictya*, as well as robust forbs and shrublets. *Combretum* spp. retaining leaves quite late into the dry season may also be important during this period. By the late dry season when little green foliage remains, Greater Kudus consume even the foliage of unpalatable evergreens like gwarrie (*Euclea* spp.) that are high in condensed tannins, although in limited amounts. The leaf succulent Spekboom *Portulacaria afra* forms the year-round staple in Eastern Cape thickets (Zeeman 1991). Greater Kudus are renowned for eating certain plant species reputed to be poisonous, including the large succulent leaves of *Euphorbia* and *Aloe* spp. Grasses are consumed in limited amounts when green, with animals selecting the most nutritious species (e.g. *Panicum maximum*) or green flush on burns. Occasional stomach samples may contain 30% or more grass (Conybeare 1975). Flowers are also eaten, especially those produced abundantly ahead of leaves (e.g. Wild Pear *Dombeya rotundifolia*), or exceptionally large (Sausage Tree *Kigelia pinnata*).

Chemical analyses suggest that the prime factor distinguishing unpalatable woody browse is a high content of condensed tannins relative to protein in leaves (Cooper *et al.* 1988). Some high-tannin species are readily consumed in the new leaf phase when protein levels are elevated relative to tannin contents. Hydrolysable tannins prevalent among the Combretaceae do not seem to be a deterrent (Owen-Smith 1993d). Unpalatable species commonly show low fibre digestibility *in vitro*, presumably because condensed tannins or other secondary chemicals interfere with bacterial fermentation

(Boomker 1987). Greater Kudus rarely browse woody stems lacking leaves, but eat many forbs whole. Males use their horns to pull down branches, thereby bringing leaves within feeding reach. Dietary protein levels vary from 12 to 14% during the late wet season to 9% by the late dry season (Owen-Smith & Cooper 1989). Dietary fibre content varies from 40 to 55%, total phenolic content 3.3–6.6% and condensed tannins 1.8–3.5%. Kudus sometimes chew on bones, suggesting a deficiency of phosphorus or calcium, and also lick white sodic encrustations near pans (Conybeare 1975).

Food availability becomes considerably depleted during the dry season when deciduous trees shed their leaves (Owen-Smith 1994), and kudus can lose considerable body reserves over this period (Wilson 1970, Huntley 1971).

Social and Reproductive Behaviour Greater Kudu ♀♀ and young live in cohesive social groups or clans sharing a common home-range. In Kruger N. P., the modal social clan size is 7–10 (range 3–21), comprising 4–6 adult ♀♀ (range 2–11) plus juveniles, yearlings and young ♂♂ up to two years of age (Owen-Smith 1984, see also Underwood 1978). Clans larger than ten animals are frequently split into sub-units, so that the observed group size is typically 6–7 (range 1–21) in Kruger N. P. Larger aggregations may occasionally be seen when social units mingle temporarily. Group size tends to be largest during the early dry and early wet seasons, and smallest during the calving period in the late wet season. In Hwange N. P., Zimbabwe, a modal group size of 5–6 (maximum 19) was recorded (Conybeare 1972; see also Simpson 1968). In the Eastern Cape, the typical female group size was about five (range 2–11; Perrin 1999). In areas where the species is hunted, the modal group size is about four (Wilson 1965, Du Plessis 1986).

Female home-ranges cover 3–25 km² in Kruger N. P. (Owen-Smith 1984, du Toit 1988), but can be as small as 1 km² in succulent thicket (Perrin & Allen-Rowlandson 1993) and exceed 25 km² in parts of Zimbabwe (D. H. M. Cumming pers. comm.). Home-ranges of neighbouring social units overlap extensively, but with an exclusive core area that is not defended in any overt way. The extent of the home-range utilized expands in the wet season, when some habitats become temporarily favourable, and contracts during the dry season to sections containing more persistent browse, such as water-courses and hillslopes. Young ♀♀ generally remain within their mother's clan, forming extended matriline. Dispersal between clans occurs at a low rate of about 0.5% per ♀ per year. Large clans may eventually subdivide and partition the former home-range.

Some social units have an obvious leader, generally an older ♀ that tends to move independently and is followed by other group members. Aggressive gestures, like butting, generally take place between an adult and a young animal that is not her offspring, and there is little evidence of any dominance ranking among mature ♀♀. Allogrooming occurs commonly. Group members maintain contact through hearing as well as visually, and can track down companions by following their scent trail over some distance. Tail flagging displaying the white underside is a signal given when starting to move on, and also when fleeing from a predator. When different social units meet, their members largely ignore one another, and may mingle temporarily without losing their group affiliation.

Adult plus subadult ♂♂ form loose groups typically numbering 3–4 animals, both in Kruger N. P. (Owen-Smith 1993c) and in

Greater Kudu *Tragelaphus strepsiceros*.

Eastern Cape (Perrin 1999). The largest male group recorded in Kruger N. P. study areas numbered 12 animals, but as many as 16–25 ♂♂ have been seen together elsewhere (N. Owen-Smith pers. obs.). Older ♂♂ tend to become increasingly solitary. In Kruger N. P., ♂♂ move over large home-ranges covering perhaps 50 km², while in the succulent thickets of Eastern Cape male home-ranges averaged 1.6 km² (max. 2.7 km²; Perrin & Allen-Rowlandson 1993). There is no territorial exclusion, and ♂♂ may roam beyond the area they normally inhabit to seek out ♀♀ during the mating season.

The onset of mating activity is evident merely through the attachment of mature ♂♂ to the female herds. Males do not advertise their presence vocally. In contrast to the active rut shown by Red Deer *Cervus elaphus* and other northern ungulates, Greater Kudu bulls show little reduction in their feeding time during this period (Owen-Smith 1984). Males remain associated with a particular group of ♀♀ for a week or two, presumably after detecting that some members are about to come into oestrus. Attachments are temporary as bulls shift between different female groups as well as spending periods alone during the conception period. More than one bull may be associated with a female herd, but invariably only one of these is a fully mature ♂, the others being younger hangers on. The latter are tolerated through an age-graded ranking in dominance. Upon meeting, one or both ♂♂ may adopt a hunched broadside posture with elevated manes, designed to emphasize size. The incoming ♂ may merely walk past seeming not to notice, seem distracted by various itches, or circle slowly round the displaying ♂. Thereafter both animals relax, but sometimes fights develop when equal-sized rivals meet. The spiral horns lock the bodies of the combatants as they push and twist in a test of power and strength. The loser departs from the scene, followed a short way by the victor. Occasionally, the horns get so inextricably tangled that both animals die.

While associated with a female group, the ♂ periodically solicits urine samples, approaching with soft bleats to press his nose into the perineal region of the ♀. Frequently, this results in the ♀ ejecting a small amount of urine, and the bull mouths the liquid followed by the flehmen or lip-curl action. Oestrus is indicated by the formation of a tending bond between the bull and a particular ♀, with the pair occasionally separating from the herd. Courtship actions by ♂♂ include standing head held high, sometimes with the nose pointing skywards, behind or beside the ♀, and stretching the neck over her back (see Walther 1964a). Mating is not attempted until the ♀ is ready. Copulations are brief, lasting 5–14 seconds, including pelvic thrusts. Tending bonds usually last a day or less, but occasionally extend over two days (Owen-Smith 1993c).

Young animals lie out after birth, not moving with the herd until 8–10 weeks old. The mother leaves the herd each day to seek out the offspring where she last left it. Once in the vicinity she gives soft moos, and the baby bounds from its hiding place to join her. While the calf is suckled the mother licks the perineum, and consumes urine and faeces that may give away the offspring's presence. After nursing the baby moves away to hide itself again. As calves get older they move for a period with the mother (and later with the herd) before they hide, so that the location of the hiding place changes daily. The mother seems not to notice when her offspring hides, yet encounters no difficulty in relocating it from day to day. Within the herd, calves tend to move as a sub-unit rather than following closely after their individual mothers.

A loud bark is used as an alarm call, given when a human or a predator is detected. When a predator is in clear view Greater Kudu may move off without any call. When suddenly disturbed the herd may scatter and reassemble later. In contradiction of some reports, barks seem not to play any role in spacing herds.

Reproduction and Population Structure In Kruger N. P., the peak mating season extends through Apr into May, with calves born mostly during Jan and Feb, but some out-of-season conceptions and births occur in other months (Owen-Smith 1984, 1993c). In the Eastern Cape, most births occurred between Dec and Feb, while adult ♂♂ were seen associated with ♀♀ between Apr and Jul (Perrin 1999). In Zimbabwe and Zambia, the peak calving months are Feb and Mar, with some calves born as late as May (Wilson 1965, Simpson 1968). In captivity, they also exhibit seasonal breeding, with a peak in Mar, but some calves born as late as Jul (Skinner *et al.* 2002). Young are thus conceived when ♀♀ are in prime condition at the end of the wet season, and born during the time when forbs and other high-quality browse are most abundant.

A gestation period between 259 and 271 days is indicated by records for captive animals (Dittrich 1972) as well as by the months of observed matings and births (Owen-Smith 1993c, Perrin & Allen-Rowlandson 1995). A single young is the rule, with the birth mass of 16 kg representing 9% of maternal mass (Allen-Rowlandson 1980). Occasionally, two calves may nurse from the same ♀, but whether these represent twins or allofostering is unclear. Calves commence browsing when 6–8 weeks old, and are weaned around 6–7 months of age.

Females generally first conceive at 2.3 years of age and bear their first offspring at three years, but in some populations up to half reproduce a year earlier (Perrin & Allen-Rowlandson 1995). Females are capable of breeding annually, but with apparent variation in fertility among individuals within clans. Conception rate approaches 100% among prime-aged ♀♀. On average only about 50% of calves survive to the end of their first dry season, with most losses occurring perinatally before young emerge from the lying out period. Calf survival is strongly dependent on the annual rainfall total over the preceding year, which probably controls foetal growth during late gestation as well as the mother's milk supply after parturition via the amount of high quality forage available (Owen-Smith 1990). Maternal mortality averages about 8% per year during the prime stage from two to six years of age, mostly due to additive predation. Thereafter, the mortality rate rises as senescence takes effect (Owen-Smith 1993a). Potential longevity in the wild is 15 years for ♀♀.

Males commence spermatogenesis around 18 months of age (Perrin & Allen-Rowlandson 1995). They generally break away from their maternal unit around two years of age, although some individuals may remain associated with their mother's herd for up to a year longer. Thereafter ♂♂ move initially in pairs or larger associations of similar aged animals, temporarily joining up with older ♂♂. Individual affiliations become less persistent as ♂♂ grow towards maturity. Apparently playful sparring between ♂♂ in these shifting groups may facilitate the assessment of relative size and hence dominance. Males do not attain full horn growth and weight, and hence prime dominance status, until six years of age (Owen-Smith 1993b).

Annual mortality rates climb as ♂♂ grow larger than ♀♀ after two years. By six years of age, a ♂ has only a 50% chance of surviving

another year (a mortality rate comparable to that of a 12-year-old ♀), and no ♂ older than nine years was recorded in Kruger N. P. (Owen-Smith 1993a). Hence, few bulls retain prime breeding status for longer than two years. In captive conditions, Greater Kudus may live to be much older: Jones (1993) gives a longevity record for *T. s. strepsiceros* of just over 22 years.

As a consequence of the male-biased mortality the population sex ratio is strongly skewed towards ♀♀. For all adults plus subadults older than two years, the sex ratio varies between 2.1 and 2.5 ♀♀ per ♂ among different populations (Owen-Smith 1993a). However, the operational breeding ratio of prime-aged (>6 years) ♂♂ to receptive (>2 years) ♀♀ is 1 : 12. Since there are barely enough bulls to go around among female groups (effectively one mature bull for every 2–3 female units), ♂♂ rarely need to contest dominance through overt aggression or territorial exclusion. Five-year-old bulls even get mating opportunities when no older ♂ is present. This system was called ‘mating enhancement by attrition of rivals’ (Owen-Smith 1993b). The prime cause of the differential male mortality is not clear. It seems basically a consequence of larger-than-optimal body size, with larger size benefiting reproduction at the cost of survival. Costs probably arise through malnutrition as well as lessened agility in evading predators. Unlike many other ungulate species, Greater Kudu ♂♂ show relatively little reduction in foraging time during the breeding period (Owen-Smith 1984).

Greater Kudus are susceptible to mortality when cold wet spells occur at the end of the winter dry season in southern Africa (Wilson 1970, Simpson 1972a). In Kruger N. P., a maximum daily temperature of 14 °C associated with overcast conditions, rain and wind resulted in a doubling of adult mortality from 10% to 20%, especially among old ♀♀, and reduction in calf survival from 60% to 25%, despite prior good rainfall (Owen-Smith 2000).

Predators, Parasites and Diseases Greater Kudus, or at least ♀♀ and young, are subject to predation by all the larger carnivores, including Lions *Panthera leo*, Spotted Hyenas *Crocuta crocuta*, Leopards *Panthera pardus* and African Wild Dogs *Lycaon pictus*. They usually are not the major prey species for any of these predators, except in areas where abundant (e.g. see Pole *et al.* 2004). Even though predation is the direct cause of death of almost all animals, except during severe droughts, it is generally interactive with nutrition because of the strong correlation between the mortality rates of all except the prime age class and rainfall relative to population density (Owen-Smith 1990).

Greater Kudus are among the main hosts of tsetse flies, although they do not seem to suffer ill effects from the trypanosome microparasites transmitted by these flies. They seem especially susceptible to several wildlife diseases causing severe mortality during outbreaks. Greater Kudu were among the ungulate species decimated during the rinderpest panzootic that spread through Africa during the 1890s (Mack 1970, Rossiter 1994). Animals in E Kenya were adversely affected by a rinderpest epidemic in 1993–97 (Kock *et al.* 1999). The species seems to be centrally involved in spreading anthrax during outbreaks of this disease in Kruger N. P., as well as suffering severe mortality, resulting in a population decline by as much as 40% in infected areas (De Vos & Bryden 1996, Bengis *et al.* 2003). Greater Kudus pick up spores through feeding on leaves where blowflies have defecated after feeding on infected carcasses. However, in Etosha N. P. in Namibia,

where anthrax is endemic, Greater Kudus make up a very small proportion of the animal deaths (Lindeque & Turnbull 1994). Rabies caused severe mortality among Greater Kudus in Namibia in 1981, amounting to 16–20% of the estimated population per farm, and up to 50% losses in some areas (Hassel 1982). Transmission seems to occur via salivary contamination of browse, and the outbreak was associated with an abnormally high density of Greater Kudus at that time. Greater Kudus also suffer from bovine tuberculosis, and may play a role in maintaining the disease in the system (Bengis *et al.* 2003). They also appear to be very susceptible to Bovine Spongiform Encephalitis (Cunningham *et al.* 2004).

Greater Kudus carry high tick loads, especially of *Boophilus decoloratus*, *Amblyomma hebraeum* and *Rhipicephalus* spp. (Horak *et al.* 1992b, Gallivan & Surgeoner 1995, Zieger *et al.* 1998b). The Red-billed Oxpeckers *Buphagus erythorynchus* that commonly clamber over them probably play an important role in controlling the tick burdens, along with the reciprocal grooming that Greater Kudus show. They are also subject to bites from swarms of tabanid flies as well as tsetse flies (Boomker *et al.* 1989b, N. Owen-Smith pers. obs.), probably on account of their comparatively sparse hair coat.

The nematode roundworm burdens carried by Greater Kudus are somewhat lower than those found in grazing ungulates. Species commonly found include *Haemonchus veglii* and *Cooperia neitzi*, *Cooperia acutispiculatum*, *Cordophilus saggitus* and *Trichostrongylus deflexus* (Boomker *et al.* 1988, 1989b). Lactating ♀♀ may show substantially elevated worm loads, but no increase in nematode numbers was evident in a drought year.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Greater Kudus are much sought after by hunters, both for the magnificent horns of bulls and more generally for their high-quality meat. Populations seem to be quite resilient to hunting pressure, aided by their alert and reclusive habits and their apparent ability to persist in settled areas that have suitable cover. They are also a favoured game-ranching species, because as browsers they do not compete with domestic livestock. In southern Africa, Greater Kudus are common on private farms and conservancies; East (1999) estimated that some 60% of the global population occurs on private land, and they seem to be expanding their distribution outside protected areas.

In the southern and south-central parts of their range, Greater Kudus are generally well represented in protected areas, with important populations in Ruaha N. P. and Rungwa and Selous Game Reserves (Tanzania), Luangwa Valley and Kafue National Parks (Zambia), Etosha N. P. (Namibia), Chobe G. R. (Botswana), Hwange and Mana Pools National Parks (Zimbabwe), Niassa G. R. (Mozambique) and Kruger N. P. (South Africa). However, in the northern parts of the species' range, the Greater Kudu seems to be in decline, with its status threatened further by the species' fragmented distribution and susceptibility to diseases transmitted by cattle. Key populations in this part of the range include those in Zakouma N. P. (Chad), Nechisar, Omo, Mago and Awash National Parks (Ethiopia), Laikipia and Tsavo N. P. (Kenya) and Tarangire N. P. (N Tanzania) (East 1999).

Tragelaphus buxtoni MOUNTAIN NYALA (GEDEMSA)

Fr. Nyale des montagnes; Ger. Bergnyala

Tragelaphus buxtoni (Lydekker, 1910). Nature 84: 397. Ethiopia, Bak Prov., 'Arusi plateau of Gallaland, in the Sahatu Mountains, and south-east of Lake Zwei [Zwai], at an estimated height of 9000 feet [2700 m] above sea level'.

Mountain Nyala *Tragelaphus buxtoni* male.

flank and spiral horns with a strong posterior keel, but of stockier build, thicker neck and heavier horns. Adult ♂ ♂ have a dun brown coat, which gets progressively darker with age, with white markings on face, throat, legs and poorly defined stripes on back and upper flanks. Coat texture varies, possibly by season, from sleek to shaggy; hair in back of thighs longer and stiffer. An erectile white crest or mane, 100 mm high, runs from neck to tail; the bushy tail reaches the heel. Females smaller and lighter in colour, resembling a Red Deer hind in size and proportions; dark greyish-brown coat, with paler undersides, white markings on legs and face and faint spots and stripes; erectile crest absent. Young cows bright rufous, with older cows as grey as a young bull. Ears large, lined with tracts of white hairs and a narrow black smear-like mark on the lower margin. Only ♂ ♂ have horns, which are lyre shaped, and grow outwardly in a spiral with 1–2 turns, a distinctive back ridge, and sometimes having ivory tips. Females have two pairs of inguinal nipples.

Geographic Variation None recorded.

Similar Species

Tragelaphus strepsiceros. Drier wooded areas of Ethiopia, potentially sympatric on some mountain slopes. Taller, colour paler and more graceful; horns longer, with 2–3 spirals and tips more separated.
T. angasii. Southern Africa only, in Malawi, Mozambique, Zimbabwe and South Africa. Smaller and readily distinguishable by an abundant fringe of long hair on throat and neck; horns similar, although slender and narrower.

Taxonomy Monotypic. Described from a specimen brought to England in 1908 by Major Ivor Buxton, the Mountain Nyala is the last major large mammal to be discovered in Africa. Despite its common name, studies involving nuclear DNA reveal that the species forms a monophyletic clade with the Bongo *T. eurycerus*, Sitatunga *T. spekii* and Bushbuck *T. scriptus*, all species adapted to closed forest (Willows-Munro *et al.* 2005). Synonyms: none. Chromosome number: not known.

Description A large tragelaphine similar in appearance and size to the Greater Kudu *T. strepsiceros*, sharing a row of spots along the

Distribution Endemic to Ethiopia. Restricted to a few scattered populations alongside an arc of mountains south-east of the Rift Valley, between 6°N and 10°N. Formerly occurred from Gara Muleta in the east to Shashamane and north Sidamo in the south, but eliminated from a large proportion of its former range. Presently, up to half of the world population is found in the Bale Mountains and the eastern escarpments of the Bale massif (Shedem, Odo Bulu, Abasheba). Smaller relict populations occur in Chercher (= Amhar) Mts (Kuni-Muktar, Arba Guggu, Din Din), Arsi Mts (Chilalo, Galama, Mt Kaka, Munessa) and West Bale (Somkaro-Korduro ridge) (Hillman 1988a, East 1999, Malcolm & Evangelista 2005).

*Tragelaphus buxtoni*

Habitat Ideal habitat is provided by montane woodlands (3000–3400 m), dominated by *Juniper*, *Podocarpus* and *Olea* in the lower parts and *Hagenia*, *Juniper* and *Hypericum* in the upper reaches. Mountain Nyalas frequent the fringes of montane grasslands (2800–3100 m) dominated by sage brush *Artemisia afra*, red-hot pokers *Kniphofia foliosa* and everlasting *Hypericum* spp. Highest densities (up to 21 ind/km²) have been recorded in the montane grasslands of Gaysay, Bale, where there is a combination of browse and grass with woodland cover to retreat into during the day (Hillman & Hillman 1987).

What were formerly large continuous blocks of suitable woodland and afroalpine habitat have now been reduced to a series of habitat islands in a sea of cultivated fields. It appears likely that Mountain Nyalas have been forced into even higher areas due to human increase and livestock grazing, with animals also found above 3400 m on heath forest and ericaceous heath lands (*Erica* and *Phyllippia* spp. with *Hypericum*, *Euphorbia* and *Helichrysum* shrubs) and on afroalpine grasslands (*Alchemilla* spp., *Festuca* spp.) up to 4300 m. In the eastern extreme of its distribution, a relict population was recorded in forests as low as 1800 m (Bolton 1973); the Munessa population occurs at 2400 m (Malcolm & Evangelista 2005).

Abundance The world population of Mountain Nyalas was estimated at 7000–8000 (and perhaps even as high as 12,500) in the 1960s by Leslie Brown (Brown 1969a), and at between 2000 and 4000 individuals in the 1980s (Hillman 1988a). Global numbers have declined since. Habitat suitability projections indicate that there may be as little as 8333 km² (Atickem *et al.* 2011) or up to 40,000 km² (Evangelista *et al.* 2008) of forest habitat available to the species, but the latter estimate includes many areas heavily impacted by human activities. Mountain Nyalas are possibly extinct in the eastern and southern extremes of their distribution, but small numbers may still occur in Asba Tafari and in the border between Bale and Sidamo south of Kofele. The total population was calculated by East (1999) at 2650, but subsequent

Lateral and palatal views of skull of Mountain Nyal *Tragelaphus buxtoni*.

information indicates that this may be an overestimate. The main extant population occurs in and around the Gaysay grasslands in the northern extreme of the Bale Mts, where numbers have been monitored since 1983. In response to the creation of a national park in the 1970s, which provided protection from poaching and the exclusion of cattle grazing, the Mountain Nyal population in Gaysay increased to 1050 by the late 1980s (Hillman 1988a). Woldegebriel (1996) put the population prior to 1990 between 1500 and 1900. Unfortunately, as a result of the political unrest that followed the end of the war in 1991, most Mountain Nyal habitat in northern Bale was encroached by cattle and there was extensive shooting of nyalas. Consequently, the Gaysay population decreased to only a fraction of what it was, and park staff estimated it to be 150–260 by 1994 (Woldegebriel 1996). There have been signs of recovery since, and the population was tentatively estimated in 1997 at 530–1000 using transect counts (Stephens *et al.* 2001), although this result may be biased due to transect design, and a conservative population estimate should be put close to the lower figure. More recently, the Gaysay population was estimated at 550 by Refera & Bekele (2004) and Malcolm & Evangelista (2005).

In addition to the population in Gaysay there may be as many as 80–120 Mountain Nyalas elsewhere in Bale Mountains N. P., less than 100 in adjacent hunting areas to the north of the park and 30–60 in Somkaro in W Bale (C. Sillero-Zubiri pers. obs.). Malcolm & Evangelista (2005) estimated as many as 500 Mountain Nyalas may occur in hunting blocks east of Bale. This would give a total population estimate for the Bale massif of 1000–1400. Small fragmented populations found in Arsi (Galama, Chilalo, Kaka and Munesa) and elsewhere (Kuni Muktar, Din Din, Arba Gugu) would total some 600 animals (Malcolm & Evangelista 2005). Although Atickem *et al.* (2011) estimated a population of over 3000 using faecal pellet counts, it is likely that only 1500–2000 Mountain Nyalas survive throughout the range. There are none currently kept in captivity (East 1999).

Mountain Nyala *Tragelaphus buxtoni* female.

Adaptations Mountain Nyalas are shy, rather elusive antelope, and have adapted to life in the relatively rich highland habitats, resulting in a specialized diet and physiology; they have a limited diet of montane vegetation, and have adapted to extreme temperature variation. As a result, it is likely that they are outcompeted by Greater Kudus in the surrounding arid lowlands. The animal's skeletal proportions, with relatively short distal limb segments, are characteristic of a mountain quadruped, which probably evolved in the relatively richer and varied periglacial habitats.

In a richer environment there is a premium on early reproduction and more open conflict over ♀♀. This ecological role is correlated with a relatively neotenic horn morphology. Males have lyrate horns that provide an effective jabbing weapon for male–male contests, but are ineffective as defensive shields. Mountain Nyalas living in continuous forests at lower elevations have an extra second spiral, suggesting that populations living in more stable lower productivity habitat may be more similar to the Greater Kudu in life history parameters (J. Malcolm pers. comm.).

Foraging and Food Mountain Nyalas are mainly browsers, and were classified as such by Gagnon & Chew (2000) in their review of the dietary preferences of African bovids. They are selective feeders, feeding on low-growing herbs and sprigs of shrubs and bushes, and tree foliage, with more grasses eaten during the early wet season. Favoured species include *Artemesia afra*, *Hypericum revolutum*, *Kniphofia foliosa*, *Solanum sessilistellatum* and *Hagenia abyssinica* leaves, which they either pick from the ground or use their horns to bring branches within their reach.

On the afroalpine grassland, Mountain Nyalas frequently eat *Alchemilla rotti*, *Helichrysum splendidum* and the lower leaves of *Lobelia rynchopetalum*. They sometimes feed on the site of a fresh burn or on the lush green of abandoned homesteads, and have been observed eating lichens, ferns and aquatic plants (Hillman 1986a).

Mountain Nyalas spend the night in the forest fringes where they probably feed part of the time, coming out early in the morning and late afternoon to feed in the grassland fringes, using the woodland and heather thickets during the hotter and colder times of the day. However, some animals often feed briefly in the middle of the day, laying down between feeds. This pattern is probably determined by the weather, with animals preferring to stay in cover during frosts and midday heat and coming out when it is overcast or raining. In the dry season (Nov–Mar), when the grassland is in poor condition, many Mountain Nyalas

move up into wooded areas and into the thick ericaceous heath. They move mostly at night to avoid human disturbance by day.

Social and Reproductive Behaviour Mountain Nyalas have a highly cohesive basic social group consisting of an adult ♀, accompanied by her calf of the previous year, and a calf of the current year. Family units aggregate with others for short periods of time to form small herds of 4–5 (mean group size = 9) (Hillman 1986a). Apparently, herds have always been small, even when the species was more common, with herds of 4–12 reported by Maydon (1925). Larger more fluid groups of up to 100 animals are often seen in Bale, with family units moving in and out (Hillman 1988a). Size and longevity of these larger groups varies with season, habitat type and time of day. Female–young groups are often monitored by adult ♂♂, depending on the presence of oestrous ♀♀. Young ♂♂ leave the family herds at around two years of age and join other adult and young bulls to form bachelor groups of up to 13 animals (Hillman & Hillman 1987).

Circling dominance display by male Mountain Nyala *Tragelaphus buxtoni*.

Males are not territorial, and have home-ranges of 15–20 km² in the wet season, with ♀♀ and juveniles using smaller wet season home-ranges of 5 km² (Hillman 1986a). Dry season ranges are significantly larger for both sexes. A dominance hierarchy is apparent in male herds, maintained by pushing and tussling of horns in the young and ritualized displays in the older ♂♂. Old bulls live alone, occasionally approaching a herd to check for receptive ♀♀. More ♂♂ are associated in mixed-sex groups during the period when most mating, pre-mating and follow-up behaviour takes place. Although intense following is occasionally observed throughout the year bulls are more likely to be seen alone during the dry season.

Bulls follow receptive ♀♀ persistently and test their vulvas, followed by flehmen behaviour. Often, 3–4 bulls follow in ritualized parallel walks. When two evenly matched bulls meet, they engage in a wary circling dance. They move very slowly, with strutting gait and head lowered, their spinal crests and fluffed tail raised. Sometimes the strut gives way to a stiff sideways shuffle, until eventually smaller ♂♂ give way and drift away. Less often the ♂♂ take the challenge with a brief heated clash of horns. Rutting ♂♂ engaged in these ritualized walks often carry 'decorations' of soil, branches and grass tussocks hanging off their horns.

Calves lie up for several weeks in cover, later rejoining their mother. Mountain Nyalas are mainly silent, but ♀♀ may utter a low bark when alarmed or 'cough' when the threat is less serious (Brown 1969a).

Reproduction and Population Structure Females first mate at two years of age, giving birth to a single calf about 8–9 months later. In Bale, calving takes place throughout the year, with a peak of births (70%) from Sep to Nov, towards the end of the wet season (Hillman 1988a). There is a high calf to adult ♀ ratio, suggesting a calving rate of at least 50%, and a high survival rate of calves (Hillman 1986a).

Predators, Parasites and Diseases Possible natural predators include Leopards *Panthera pardus*, Spotted Hyenas *Crocuta crocuta*, Servals *Leptailurus serval*, Ethiopian Wolves *Canis simensis* and domestic dogs. The latter two species have been known to kill Mountain Nyala calves in and around the Gaysay grasslands in Bale (Sillero-Zubiri & Gottelli 1995, Woldegebriel 1996), but there are no records available for the other species. None is thought to have a serious effect on adult Mountain Nyalas (Brown 1969a). Lions *Panthera leo* could take adults, but they are not common in Mountain Nyala range. Calves and juveniles may be taken frequently by Leopards and Spotted Hyenas at night but the effect on survival, if any, is unknown.

Almost nothing is known regarding diseases in Mountain Nyalas, although they are susceptible to rinderpest (Fekadu Shiferaw pers. comm.). Females are often found dead during the wet season in Bale, showing symptoms compatible with those of poisoning from eating certain vegetation. Graber *et al.* (1980) recorded a fluke (*Cotylophoron cotylophoron*) and two nematodes (*Oesophagostomum walkeri* and *Haemonchus vegliai*).

Conservation IUCN Category: Endangered C1. CITES: Not listed.

Threatened directly by illegal hunting and indirectly by disturbance and destruction of montane forest and heath lands, encroachment by cattle, harassment and hunting by dogs, high-altitude cultivation, and roads. In the past, Mountain Nyalas were often seen living alongside pastoralists when the latter were present at low densities (Maydon 1925). However, permanent occupation of suitable habitat as a result of increasing human pressure and livestock populations is exerting tremendous pressure on Mountain Nyala habitat throughout the range, with anecdotal evidence suggesting the animals actively avoid livestock (C. Sillero-Zubiri pers. obs.).

This pressure is also apparent within Bale Mountains N. P., home to 60–80% of the world's Mountain Nyala population, and which was created primarily to protect the Mountain Nyala (Brown 1969a). The impact of effective conservation measures in northern Bale during the 1970s and 1980s was phenomenal, and the Mountain Nyala population flourished as a result of the exclusion of domestic stock (Hillman 1986a). Unfortunately, a decline in (and at times collapse of) park management during the 1990s resulted in human encroachment, overgrazing, illegal hunting and Mountain Nyalas

moving out of optimal habitat. Additionally, the constant passage of people through their range disturbs their foraging habits.

Although Mountain Nyalas are fully protected by law there has been a proliferation of hunting licences issued out to hunting concessions around Bale. The absence of enforcement and the general ignorance of protective legislation among the local people, and the failure of police and other officials to make any serious attempt to enforce the law, restrict effective protection to a small area of habitat (20 km²) in Gaysay and around Bale Mountains N. P. headquarters. Elsewhere, Mountain Nyalas are extensively hunted for meat and horns, the latter used for local medicine and to make teats for traditional milk bottles.

Conservation action required in Bale Mountains N. P. and adjacent hunting areas includes the enforcement of patrolling to curb cattle grazing and the protection of the Mountain Nyala population from illegal hunting. The park should ideally be extended northward to include suitable habitat within hunting blocks. There is also a need to extend patrolling to the higher-altitude areas of the park, where uncontrolled livestock grazing needs to be checked. Elsewhere illegal hunting needs to be controlled throughout the Arsi Mts, where the recent establishment of an additional protected area may deliver some conservation benefit for the species. Although it has been argued that high licence fees may finance conservation measures and derive a benefit to local people the current quota of adult bulls made available for trophy hunting may be unsustainable in the long term. Hunting blocks in Arsi have been hunted out and concessions moved to Bale, with continued pressure by the industry for additional hunting blocks and larger quotas. While legal hunting is restricted to adult ♂♂, trophy size needs to be monitored carefully. Absence of old bulls or a sex ratio imbalance may affect reproduction and population dynamics.

Tragelaphus scriptus BUSHBUCK

Fr. Guib Harnaché (Antilope Harnaché); Ger. Schirrantilope

Tragelaphus scriptus (Pallas, 1766). Misc. Zool. p. 8. No locality cited but based on 'Le Guib' of Buffon, from 'Sénégal'.

Senegal Bushbuck *Tragelaphus scriptus* (*scriptus* group).

Taxonomy No fewer than 27 subspecies were recognized by Allen (1939) and this was reduced to 23 by Haltenorth (1963); only nine were accepted by Ansell (1972). Kingdon's (1997) treatment largely echoed that of Ansell (1972), except that he did not recognize *powelli* (which Haltenorth [1963] had included in *decula*), and accepted two subspecies found in the montane regions of E Uganda (*barkeri* and *heterochrous*, which Ansell [1972] included in *bor*) for a total of ten subspecies. Grubb (1985) recognized six subspecies in East Africa, and Meester *et al.* (1986) three from southern Africa. Most of the variation within the species has been analysed based on coat colour, patterns of black/dark brown and white markings on the legs, lower shoulder, belly line and haunches, and patterns of spotting and stripes. It might be that some of the characteristics are controlled by hormones or diet given the large variation that can occur even at a single site (Kingdon 1982).

Recently, continent-wide variation in the Bushbuck has been investigated using mitochondrial markers (control region, cytochrome *b*) revealing that the Bushbuck comprises two genetically divergent lineages: a *scriptus* group from the north-western half of the continent, and a *sylvaticus* group from the south-east (Moodley & Bruford 2007). Further molecular analysis (Moodley *et al.* 2009; and see Hassanin *et al.* 2012) suggests that these may represent two distinct species as suggested by early taxonomists (e.g. Sclater & Thomas 1899/1900). The subspecific taxonomy adopted here is a combination of several taxonomies, principally those suggested by Grubb (1985, 2005) and Meester *et al.* (1986), with modifications from Kingdon (1997) and the study by Moodley & Bruford (2007). Synonyms: *barkeri*, *bor*, *brunneus*, *cottoni*, *dama*, *decula*, *delamerei*, *dianae*, *dodingae*, *eldomae*, *fasciatus*, *fulvochraceus*, *gratus*, *haywoodi*, *heterochrous*, *insularis*, *johannae*, *knutsoni*, *laticeps*, *locorinae*, *makalae*, *massaicus*, *meneliki*, *meridionalis*, *meruensis*, *multicolor*, *nec*, *nigrinotatus*, *obscurus*, *olivaceus*,

ornatus, *phaleratus*, *pictus*, *powelli*, *punctatus*, *reidae*, *roualeyni*, *roualeyni*, *sassae*, *signatus*, *simplex*, *sylvaticus*, *tjaderi*, *typicus*, *uellensis*. Chromosome number: 2n = 33 for ♂, 2n = 34 for ♀ (Wallace 1977).

Description A medium-sized antelope with a great variation in coat colour and patterning across its wide geographical range. Head red or brown with white spots or flashes on the cheeks below the eye. Ears large with white around the rim and black flash inside the ear towards the base contrasting with the pink above it. Females and young are generally red whereas adult ♂♂ become progressively darker with age, sometimes to a dark brown and almost black. All age/sex groups have a white belly extending back to a broad, woolly tail that is red/brown above and white below. A dorsal crest of lighter coloured hair is present down the back of the animal. Legs are long and thin, with white fetlocks above black hooves. Hindquarters are more developed than the forequarters. The back is rounded due to shorter forelimbs (metacarpus is 20% shorter than metatarsus; Hofmann 1973). Western forms have a 'harness' with vertical and horizontal white body stripes whilst the eastern and southern 'sylvan' populations are plainer with fewer light streaks or spots on the flanks or haunches. Some montane forms have longer hair around the neck and face. Young are similar in colour to adult ♀♀ but stripes are more marked. Males are larger in body size than ♀♀, sometimes up to 50% larger (Wilson & Child 1964). Females have two pairs of inguinal nipples.

Only ♂♂ bear horns, which are smooth and have one twist in the spiral and can be straight or slightly kinked. Simpson (1973), who discussed tooth replacement and wear in *T. s. ornatus*, recorded cases where skulls had supernumerary teeth (one specimen had 16 premolars, four of which probably developed from the twinning of tooth buds).

Geographic Variation Based on molecular data, Bushbucks can be grouped into two main groups: a *scriptus* group that includes most of the Bushbucks found in West and central Africa, and which tend to be more clearly striped and spotted, and a *sylvaticus* group that is found in East and southern Africa and is generally plainer in coat patterns. Between these two groups several forms occur that show some intermediate phenotypic characteristics, but which can be clearly assigned, at least on genetic analysis, to one of the two groups (Moodley & Bruford 2007, Moodley *et al.* 2009). Grubb (1985) identified four main groups, including the *scriptus* and *sylvaticus* groups, and then grouped the intermediate subspecies into a further two groups, namely *decula* and *fasciatus* (but later lumped *fasciatus* with *sylvaticus*; see Grubb 2005).

Scriptus group (Harnessed Bushbucks):

T. s. scriptus (incl. *gratus*, *typicus* and *obscurus*) (Senegal Bushbuck): West Africa, from Senegal to Liberia. Males rich dark rufous with black suffusions, with vertical stripes down the back and horizontal

Bushbuck *Tragelaphus scriptus* polymorphism (see key opposite).

- N Male from Fort Portal, Uganda (*dama*)

stripes with spots on the shoulders, flanks and hindquarters; ♀♀ chestnut with fewer white stripes; this subspecies has the largest number of white markings on the body.

T. s. phaleratus (incl. *knutsoni* and *johannae*) (Kabinda Bushbuck): Cameroon, Gabon, Equatorial Guinea, W Congo R., W DR Congo. A montane form (*knutsoni*) confined to the region above the forest zone on Mt Cameroon is sometimes recognized as a separate subspecies (e.g. Grubb 2005). *Tragelaphus s. phaleratus* lies within the phenotypic range of *T. s. scriptus* (indeed, Grubb [2005] included *phaleratus* as synonymous with the nominate form), but without any blackish suffusions except on the withers and upper legs. A longitudinal band is often absent, particularly in ♀♀.

T. s. bor (incl. *cottoni*, *dodingae*, *meridionalis*, *pictus*, *punctatus*, *signatus* and *uellensis*) (Nile Bushbuck): NE Nigeria, Lake Chad, E Cameroon, Central African Republic, N DR Congo, S Sudan and NW Uganda, Ethiopian lowlands. Males and ♀♀ yellowish-brown in colour with ♀♀ yellower (in ♂♂ this contrasts strongly with black markings on belly); ♂♂ have relatively short and straight horns. Molecular data evidence intergradation with the Niger basin form (see below), with *T. s. phaleratus* in Cameroon and *T. s. dama* in NE DR Congo and NW Uganda.

T. s. decula (Abyssinian Bushbuck): N, S and W Ethiopia and parts of Eritrea. Small in size, with short horns in ♂; ♂ is dull sandy-ochre with grizzled hairs, giving appearance of dark brown or blackish-brown coat; ♀ light sandy-ochre with dark brown dorsal stripe

expanded into broad blackish saddle; few white markings on coat except an upper dorsal white stripe (Grubb 1985). Here attributed to the *scriptus* group following Moodley & Bruford (2007).

Moodley & Bruford (2007) distinguished three further distinct forms geographically intermediate between *T. s. scriptus* and *T. s. phaleratus*: two forms from the Upper Volta and Lower Volta, and a third form ranging from Togo to about the Cross R. in E Nigeria.

Sylvaticus group (Sylvan Bushbucks):

T. s. sylvaticus (Cape Bushbuck): southern and eastern coast of South Africa, from the Western Cape to S KwaZulu–Natal. Male dark brown, with hair at base of neck often lost in old ♂♂; little or no trace of white stripes on body (typical of *T. s. ornatus*), but some spots on sides of belly and hindquarters; ♀ fawn brown with some spotting as in ♂ (darker in colour than *T. s. ornatus*). Intergrades with *T. s. delamerei* and *T. s. roualeyni* in NE South Africa.

T. s. roualeyni (Limpopo Bushbuck): south-east Africa (NE South Africa, S Mozambique, E Swaziland and S Zimbabwe, E Botswana). Phenotypically intermediate between *T. s. ornatus* and *T. s. sylvaticus*. Males dark red and ♀♀ darker than *T. s. sylvaticus*; both sexes lack the vertical white stripes on the coat and are less spotted than *T. s. ornatus*. Treated as distinct by Meester *et al.* (1986), but considered synonymous with *sylvaticus* by Grubb (2005).

T. s. ornatus (Chobe or Zambezi Bushbuck). South-central Africa (N Zimbabwe and N Botswana, NE Namibia, S DR Congo, C and E Zambia, and ranging into Tanzania). Males dark red with distinct vertical stripes (up to eight) on coat and extensive white throat, and ♀♀ chestnut with fewer white stripes; both sexes have extensive white spots on shoulders and particularly the hindquarters. Due to its pronounced harness pattern, initially classified with the *scriptus* group, but more appropriately included in the *sylvaticus* group (Grubb 2005, Moodley & Bruford 2007). Treated as a distinct subspecies by both Grubb (1985) and Meester *et al.* (1986), but considered synonymous with *sylvaticus* by Grubb (2005).

T. s. dama (incl. *barkeri*, *dianae*, *heterochrous*, *locorinae*, *sassae* and *simplex*) (Uganda or Kavirondo Bushbuck): Uganda, including Mt Elgon (*heterochrous*), W Tanzania, the Albertine Rift (*dianae*) and the Imatong Hills in SE Sudan (*barkeri*). Male yellowish-chestnut to chestnut on haunches; belly and upper limbs dark grey to black; ♀ chestnut above and buff below; flank and rump spots occur with some vertical striping; large in size with large horns in ♂♂. The montane forms (*barkeri* and *heterochrous*) are considerably darker, and were considered distinct subspecies by Kingdon (1982, 1997). Intergrades with *T. s. bor* in the north: the montane forms occur in the same area as *T. s. bor*, but are separated altitudinally. Intergrades with *T. s. ornatus* in the south-west and *T. s. delamerei* in the east. This subspecies is considered synonymous with *sylvaticus* by Grubb (2005).

T. s. delamerei (incl. *eldomae*, *haywoodi*, *meruensis*, *olivaceus* and *massaicus*) (Maasai Bushbuck): C and E Tanzania, C and S Kenya, Mozambique, Malawi, E Zambia, E Zimbabwe and E South Africa. Large size, with large horns in ♂♂. Male dark brown, lighter at rump; belly and upper limbs dark brown; ♀ reddish-chestnut with yellowish cheeks contrasting with white throat. The montane form (*haywoodi*) from Mt Kenya, Kilimanjaro, Meru, Hanang and the Gregory Rift is phenotypically distinct, and is given subspecies status by Moodley & Bruford (2007). Intergrades with *T. s. dama*, but with less rump and flank spots. Treated as distinct by Grubb (1985), but later considered synonymous with *sylvaticus* by Grubb (2005).

T. s. fasciatus (Somali Bushbuck): NE Tanzania, E Kenya, E Somalia and presumably along the Juba R. into E Ethiopia. Adult ♂♂ usually greyish-ochre, sometimes brownish-grey; ♀♀ yellow-ochre; both sexes have greyish necks; relatively large in body size with large, widespread horns in the ♂; dorsal neck hairs relatively short in the ♂. Grubb (1985) regarded it as a very distinctive subspecies, though he later included it in *sylvaticus* (Grubb 2005).

T. s. meneliki (incl. *powelli*) (Menelik's Bushbuck): Ethiopian Highlands. Adult ♂ dark chocolate brown (though some are paler), with only white spots on rump as coat markings; ♀ dark russet brown with no dorsal stripe and 1–3 buffy spots on haunches; horns in ♂ relatively narrow and straight. Here attributed to the *sylvaticus* group following Moodley & Bruford (2007).

Moodley & Bruford (2007) distinguished three further forms: two in the Luangwa Valley and the middle Zambezi Valley, and a third from Angola; Angolan animals were referred to the subspecies *T. s. ornatus* by Crawford-Cabral & Veríssimo (2005).

Similar Species

Tragelaphus spekii. Swamp and swamp forest-dwelling species from central Africa and, marginally, from West Africa to Uganda, W

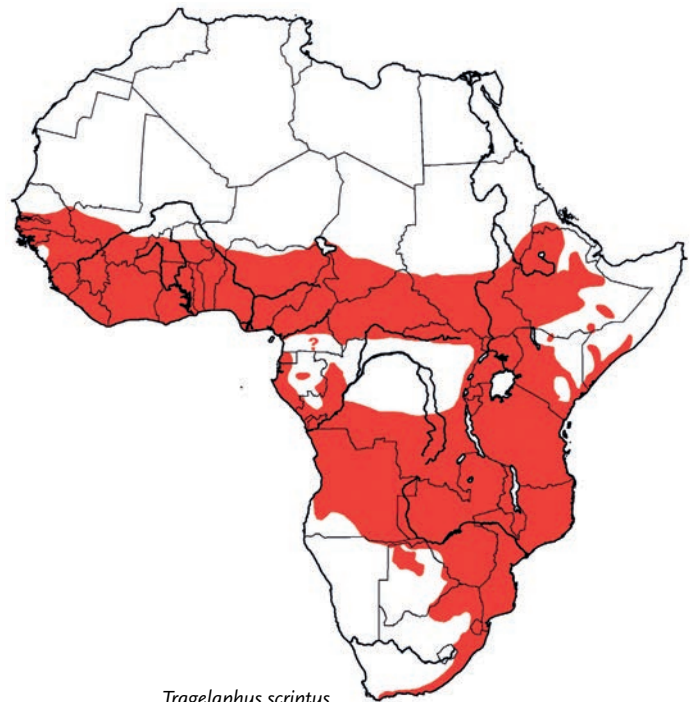

Tanzania and Zambia. Larger with longer hooves; shaggier ♀♀ are most similar but ♂♂ are darker grey/brown with long sharply keeled horns; generally found in waterlogged or swampy habitats.

T. angasii. Thicket and forest habitats of Malawi, Mozambique, Zimbabwe, South Africa and Swaziland. Larger; in ♂♂ horns longer (typically >560 mm), well-developed dorsal crest, plus fringe of long dark hair along throat and ventral surface to between hindlegs, and rufous 'socks' (carpal and tarsal) contrast with dark upper legs; in ♀♀ vertical stripes more well developed than southern forms of Bushbuck, and tail longer.

T. eurycerus. In West Africa, from Sierra Leone to Benin, and from the Sanaga R. in Cameroon along the lowland forest zone to E DR Congo; isolated montane populations exist on Mt Kenya, Mau and Eburu forests, and the Aberdares. Larger and stockier; dark russet red colour, which tends to darken on the forequarters and limbs with age; black legs with patches of white distinguish this species from the Bushbuck, which has more red/brown and white legs.

Distribution Endemic to Africa. The Bushbuck is among the most widespread of African antelopes, occurring in some 40 African countries, more than any other antelope species (East 1999). The species ranges widely from Mauritania, Senegal and Guinea-Bissau across West Africa, south of the Sahara, around the forests of the central Congo Basin to north-east Africa (SW Eritrea, W and C Ethiopia) then southwards throughout East Africa and the more mesic areas of southern Africa to around Bredasdorp in the Western Cape of South Africa (East 1999, Skinner & Chimimba 2005). It also occurs on some small islands off the African mainland including Orango N. P. in the Bijagos Archipelago off the coast of Guinea-Bissau (East 1999). The only sub-Saharan country from which it has not recently been recorded, and where it may formerly have occurred, is Lesotho (Lynch 1994).

Habitat Bushbucks occur in a wide variety of habitat types across Africa, being absent only from arid and semi-arid regions and dense

Tragelaphus scriptus

closed-canopy forest (as typical of parts of DR Congo). They range from low altitudes near the coast in southern, East and West Africa (Keep & Broker 1986, Coates & Downs 2006) up to 4000 m on the mountains of East Africa (Plumptre 1991, East 1999). Bushbucks require some cover and are most often associated with woodland, scrub and forest edges. Bushbucks appear reluctant to utilize areas away from surface water, which may be explained by them exhibiting high evaporative heat loss response, mainly due to the production of strongly diluted urine (Schoen 1971). In some areas, Bushbucks exhibit seasonal movements; in the Zambezi Valley, Simpson (1974a, b) recorded them dispersing from the riverine underbush in the warm, wet summer months (Sep–Mar), to the thickets, where water is temporarily available, returning to the riverine associations during the drier periods. In Mole N. P. in Ghana, Bushbucks preferred marshy habitat over riverine and open savanna (Dankwa-Wiredu & Euler 2002). Bushbucks are often able to survive in human-dominated landscapes such as on large farms as well as on coffee and timber (eucalypt and pine) plantations (Odendaal & Bigalke 1979, Odendaal *et al.* 1980, Schmidt 1983) and may cause severe damage to seedlings (de Zwaan 1977, Schutz *et al.* 1978). The species has disappeared from some of its former range, particularly in drier areas where habitat destruction and desertification have occurred, but is expanding where equatorial forest is being opened up by agriculture and logging, creating more forest edge and bush (East 1999).

Abundance Owing to the cryptic nature of this species, abundance is generally underestimated by aerial flights and gives densities of 0.01–0.5/km². Ground surveys (Plumptre 1991, Plumptre & Harris 1995, Mizutani 1999) and individual recognition (Jacobsen 1974, Waser 1975a, Allsopp 1978) provide very much higher, more accurate, estimates. In grassland with thickets on the Mweya Peninsula in Queen Elizabeth N. P., W Uganda, Bushbucks occurred at densities of about 26/km² (Waser 1975a), whilst in mixed-forest, bushland and grass in Nairobi N. P., Kenya, density was estimated to be similar at 30.1/km² (Allsopp 1978). In montane forest of the Virunga Mts, Rwanda, estimated densities (using faecal counts) were 11.1–44.2/km² in different habitats with highest values in or at the edge of woodland (Plumptre & Harris 1995). In riverine forest along the Sengwa R., Zimbabwe, Jacobsen (1974) recorded the highest-known densities of up to 67/km². In ground surveys that counted several species at the same time in central and western Africa, lower estimates from 0.08 to 2.0/km² have been obtained (East 1999, Fischer & Linsenmair 2001a, Brugière *et al.* 2005). For the Ethiopian Highlands (Denkoro Forest), a mean population density of 11.8/km² was reported (Yazew *et al.* 2011). East (1999) estimated total population size in Africa at about 1.34 million individuals, which is probably an underestimate.

Adaptations The widespread distribution of the Bushbuck across several habitat types implies an exceptionally adaptable physiology. The cryptic coat patterning provides camouflage in a wide variety of habitats. They apparently are excellent swimmers, taking to water to feed and also to flee from predators. Their large ears are probably an adaptation to detect predators and are particularly large in calves relative to body size. Bushbucks typically give a warning bark when danger threatens and other species use this as a warning too; baboons (*Papio* spp.) and Vervet Monkeys *Chlorocebus pygerythrus* have been

Lateral, palatal and dorsal views of skull of Bushbuck *Tragelaphus scriptus*.

recorded associating with Bushbucks as possibly a strategy to avoid predation by Leopards *Panthera pardus* (Allsopp 1971, Elder & Elder 1971, Wronski 1996). It is unclear why Bushbucks bark, given that they are principally a solitary species. It is possible that the bark indicates to a predator that it has been spotted, which may reduce the predator's likelihood of attacking. Possibly, other Bushbucks in the vicinity tend to be more related (e.g. matrilineal clan members; Wronski & Apio 2006, Apio *et al.* 2010) so their genes may be passed on more successfully as a result of warning them. Similarly, the white flashes of the underside of the tail when fleeing may also serve as a warning to others. Kingdon (1982, 1997) suggested that barks may function as indicators of rank, status, identity and physical movement within a local community of Bushbucks.

Bushbucks are the smallest of the tragelaphines, and yet have been the most successful in terms of distribution across Africa. Their small size and cryptic colouring and behaviour have probably allowed them to survive in smaller habitat patches and around human settlements better than the larger species. Cover seems to be the most limiting resource for Bushbucks, while food, competition and predation had no effect on female home-range size in Queen Elizabeth N. P. (Wronski *et al.* 2006e). Unlike other tragelaphine antelopes, Bushbuck horns are small and tend to spiral much less. This could be because this species lives in dense habitat and relies on flight into dense habitat to avoid predation (similar to strategies duikers use). It has been suggested that the horns of larger tragelaphines have evolved due to sexual selection rather than for defence (Walther 1964a) and it is possible that the Bushbuck's small size and greater vulnerability to predation has selected for smaller and straighter horns.

Foraging and Food Bushbucks are primarily browsers, tending to prefer herbs selected from between grasses, or young leaves of shrubs and trees; they also select young green leaves of grasses (Wilson & Child 1964, Jacobsen 1974, Simpson 1974c, Odendaal 1983, Allen-Rowlandson 1986, Plumptre 1995, Seymour 2002, Apio & Wronski 2005, Yazew *et al.* 2011; and see Gagnon & Chew 2000, Cerling *et al.* 2003, Sponheimer *et al.* 2003b). In a study of food preferences in South Africa, Bushbuck showed a strong selection for plants with high digestibility and low fibre content (Haschick & Kerley 1997a), but a

Bushbuck *Tragelaphus scriptus* adult female.

Bushbuck *Tragelaphus scriptus* young adult male.

relatively small bite size and bite rate (Haschick & Kerley 1997b). The preferred feeding height was determined as 52.5 ± 3.8 cm from the ground (Haschick & Kerley 1996).

In sites with strong seasonal variation, the diet seems to consist of herbs and young grass leaves in the wet season, replaced by the leaves of shrubs and trees in the dry season (Wilson & Child 1964, Jacobsen 1974, Okiria 1980, Smits 1986, MacLeod *et al.* 1996). Where there is little variation between seasons in a montane environment, herbs and grasses are selected throughout the year, particularly the grasses *Festuca schimperi*/*Agrostis* spp. and herbs, *Impatiens* and *Solenostemon sylvaticum* (Plumptre 1991, 1995). In drier areas such as Mole N. P., Bushbuck primarily consume herbs and rarely take grass unless young and green; *Raindia macaritha*, *R. captiatum* and *Eurene lobata* were the dominant foods in Mole N. P. (Dankwa-Wiredu & Euler 2002). *Dichrostachys cinerea*, *Pavetta albertina* and *Indigofera* spp. were preferred foods in Queen Elizabeth N. P. (Apio & Wronski 2005). In South Africa (Woody Cape N. R.), Bushbuck also fed on dicotyledonous herbs, in particular *Lycium afrum* and *Schotia afra* (MacLeod *et al.* 1996). Staple foods consumed throughout the year in Zimbabwe included leaves of three tree/shrub species, namely *Combretum mosambicense*, *Grewia flavescens* and *Trichilia emetica* (Jacobsen 1974), while in a study in Mpumalanga, South Africa, *Acacia nigrescens*, *Combretum heroense*, *Ficus* spp. and *Ziziphus mucronata* comprised up to 20% of the diet in all seasons (Seymour 2002). Where available, the pods of *Acacia* species and other fallen fruit are consumed, including *Ficus*, *Ricinodendron*, *Cordia*, *Balanites* and *Diospyros* (Wilson & Child 1964, Jacobsen 1974). Seymour (2002) has demonstrated how Bushbucks may be out-competed, during times of nutritional stress, by Nyalas *Tragelaphus angasii*, since the latter species is a mixed feeder with a greater browse height and

therefore has a competitive advantage in the late dry season when available browse is limited.

Mycophagy may be an important mechanism by which Bushbucks are able to exist in areas such as forests and plantations in which trace elements, such as copper, are not readily available (Odendaal 1983). Geophagia also has been recorded (Jacobsen 1974). Bushbucks may enter agricultural fields at night and in the early morning to eat crops and are considered a pest in some places. For example, around Parc National des Volcans in Rwanda they consume the leaves of potatoes, maize, cabbages, beans, peas, pyrethrum, wheat and tomato plants (Plumptre & Bizumuremyi 1996).

Where undisturbed, Bushbucks feed throughout the day and night (Waser 1975b, Wronski *et al.* 2006b) in regular cycles. Where there is a likelihood of detection and predation during the day they will feed mainly at night but may rest in dense cover, occasionally feeding during the day. Their movements are often associated with dawn and dusk. In Queen Elizabeth N. P., Bushbucks moved towards the thickets along the river at dawn, where it is presumably cooler during the heat of the day, and then back to the more open ridge at night (Waser 1975b). In the Virunga Mts, Bushbucks moved towards open meadows at dusk and back into the denser woodland and nettles during the day around the Karisoke Research Station (A. Plumptre pers. obs.) and they fed throughout the period they were in dense nettles (Plumptre 1991).

Social and Reproductive Behaviour Bushbuck are generally solitary or in pairs, with single ♂♂, single ♀♀ and male–female pairings accounting for most observations in the areas where the species has been studied: 91% in N Zimbabwe (Wilson & Child 1964), 79% in N Botswana (Elder & Elder 1971), 74% in W Uganda (Wronski 2004) and 71% in Knysna, South Africa (Odendaal & Bigalke 1979).

Other small associations usually consist of adult ♀♀, adult ♀♀ with young or subadults, or two or more adult ♂♂ (though such male groupings are both unusual and ephemeral). Larger groups of 9–12 have been recorded (Simpson 1974a, Simbotwe & Sichone 1989, Brugière *et al.* 2005, A. Plumptre pers. obs.). In the Virunga Mts, Bushbucks were generally solitary during the day when in dense vegetation but when they moved to clearings in the forest to feed in the evening it was not uncommon to see several individuals together (A. Plumptre pers. obs.). In this case the animals were not in the strict sense forming a group but were associating with each other only because of a common attraction to the same resources. They did not move and function as a coordinated group. Wronski *et al.* (2009b) compared group sizes among six different populations and found no significant difference in relative frequencies of group size categories.

A study in Uganda showed that ♀♀ are organized in matrilineal clans, sharing a common home-range and jointly defending that area against non-related ♀♀ (Wronski & Apio 2006, Apio *et al.* 2010). Home-range overlap between related ♀♀ was significantly higher than that between non-related individuals. Agonistic interactions between ♀♀ appeared significantly more often between non-related ♀♀ but rarely between kin (Wronski & Apio 2006). Moreover, ♀♀ keep close social bonds (e.g. reciprocal grooming, also between adult related ♀♀; Walther 1964a, Wronski *et al.* 2006d) and individuals communicate through localized defecation sites (mostly females to males and females to females of the same clan; Wronski 2006b). Localized defecations function neither in terms of parasite avoidance nor as a consequence of allelomimetic behaviour (Apio *et al.* 2006a).

Individual home-ranges overlap (Jacobsen 1974, Allsopp 1978, Allen-Rowlandson 1986, Coates & Downs 2005, Wronski 2005, Wronski & Apio 2006); some studies have shown that there is little defence of territories (Waser 1975a, Allsopp 1978), while others have recorded pronounced territoriality (Verheyen 1955, Walther 1964a, Jacobsen 1974). Owen-Smith (1975) discusses territoriality in Bushbuck in light of social patterns that have evolved in tragelaphine antelopes. Recent

studies have revealed further insights into the question of territoriality in Bushbuck. In a study in KwaZulu–Natal, South Africa, Bushbucks utilized a core area within their home-ranges in which 50% of their time was spent in approximately 17.0% and 11.7% of their total home-range for ♂♂ and ♀♀, respectively, and there was substantial overlap in core areas (Coates & Downs 2005). However, in Uganda, a considerable defence of 50–70% of home-range cores (territories) was observed (Wronski 2005, Wronski *et al.* 2006, 2007b, Wronski & Plath 2006). Home-range cores of adult ♂♂ did not overlap and were therefore considered exclusive areas. Moreover, adult territorial ♂♂ perform intense scent-marking (i.e. vegetation horning, front rubbing; Wronski *et al.* 2006d, 2007b) and these marked areas correspond with exclusive core areas (Wronski *et al.* 2006a). A dominance hierarchy as suggested by former studies (e.g. Jacobsen 1974) could explicitly be excluded (Wronski 2004, Wronski *et al.* 2009a). Instead, male Bushbuck exhibited two age-dependent mating tactics: adult territorial ♂♂, and young adult non-territorial ♂♂, which frequently attempt to mate with ♀♀ although they indulge in less pre-mating behaviour, herding and monopolization of ♀♀ (Apio *et al.* 2007). Males and ♀♀ advertise their presence and position by standing on termite mounds or close to vertical structures (Wronski *et al.* 2007a).

Home-range sizes vary between sites. In Nairobi N. P., small ranges of 0.25–2.0 ha were recorded, the larger ranges being occupied by juvenile animals (Allsopp 1978), whereas the home-range of a dominant ♂ in Sengwa Valley, Zimbabwe, was 5 ha (Jacobsen 1974). In an area of valley bushveld in KwaZulu–Natal, total home-range size for ♂♂, using minimum convex polygons, was estimated at 33.9 ha and for ♀♀ at 12.0 ha (Coates & Downs 2005). In Queen Elizabeth N. P., Waser (1975a) recorded home-ranges of adults varying from 6.3 to 26.5 ha for adults with one subadult ♂ having a range of 35.2 ha. In contrast to these recorded home-range sizes, average home-range size in Knysna Forest (South Africa, which is a more temperate climate) was 102 ha (Odendaal & Bigalke 1979), while Allen-Rowlandson (1986) recorded a mean

Bushbuck *Tragelaphus scriptus* display.

home-range size of 120 ha for ♂♂ and 60 ha for ♀♀ in afro-montane forest in KwaZulu-Natal. Home-range size apparently increases with decreasing density across the range of the species, and density appears to increase with an increase in rainfall during the growing season (Odendaal & Bigalke 1979).

In Queen Elizabeth N. P., animals spent 38% of their time feeding, 50% resting, immobile or ruminating and 12% moving (Waser 1975b). In the montane habitats of the Virunga Mts a similar amount of time was devoted to these activities: 50% feeding, 44% resting or ruminating, 6% walking or grooming (Plumptre 1991). Similar patterns were described for Bushbuck from Denkoro Forest in the Ethiopian Highlands (Yazew *et al.* 2011). Wronski *et al.* (2006c) investigated differences in activity patterns in relation to time of day, season, radiation, moonlight, age and sex. Bushbucks were found to show peak activities around sunrise and sunset. No difference in the mean activity rates was found between the dry and wet season. Daytime activity was not predicted by differences in sun radiation, nor was night-time activity predicted by the presence or absence of moonlight. The activity of adult territorial ♂♂ was strongly positively correlated with that of ♀♀, whereas that of non-territorial ♂♂ was not correlated with the activity of ♀♀.

As noted already, Bushbucks often associate with baboons (*Papio* spp.) at various sites across the continent and it is thought that both species benefit from the association with the Bushbuck's sense of smell and the baboon's ability to spot predators from trees (Elder & Elder 1971, Allsopp 1978, Wronski 1996). Bushbucks were accompanied by baboons in about 35% of sightings in Chobe N. P., Botswana and Nairobi N. P. (Elder & Elder 1971).

Males threaten other ♂♂ by a stiff-legged walk and lateral presentation, with the head up (Walther 1964a, Kingdon 1982, Estes 1991a, Wronski *et al.* 2006d). They raise the hairs on the dorsal crest, arch the back and raise the tail to expose the white underside and may circle each other. In Uganda, territorial ♂♂ were observed escorting intruders to the edge of their territories (Wronski *et al.* 2006d). Occasionally, a ♂ will feint attack and lower his horns and horn at the ground. If closely matched, the ♂♂ may raise the intensity of combat with head-on clashes and locking horns, and attempts made to gore the flanks of the opponent (Walther 1964a, Allsopp 1978, Wronski *et al.* 2006d). Defensively, a ♂ keeps the head low, turns away and licks the aggressor. Females also show agonistic interactions, but on a much lower scale (Wronski & Apio 2006, Wronski *et al.* 2006e). When approached by a predator, ♂♂ or ♀♀ freeze, sinking to the ground with the neck and head stretched out along the ground. If the danger is close, they sometimes bark and flee with their tails raised, exposing the white underside in a bright flash. The young have a bleat not unlike a goat's call when lost from the mother, but adults do not vocalize much other than barking.

When courting, ♂♂ nuzzle the female's genitals, lick her, rub cheeks on her rump, press the neck or head on her rump and test urine by licking the stream as it falls to the ground. In the urine test, the ♂♂ approach with neck extended and head low, with no dorsal crest showing and the ♀ responds by crouching, a position typically used in urinating with the hindlegs bent and the tail raised. Males tend the ♀ while she is receptive, chasing off other ♂♂ unless supplanted by another ♂ (Walther 1964a, Estes 1991a).

Calves are born in areas of dense cover and lie still whenever the ♀ is away feeding. They may spend up to four months like this

before venturing into more open habitat (Estes 1991a). At about 6 months of age young ♂♂ leave their mother's home-range and join a bachelor group. From this pool they challenge existing territorial adult ♂♂ until they take over a territory (Wronski 2005). Females will stay with their mothers (and other female kin) throughout life, forming matrilineal groups (Wronski & Apio 2006, Apio *et al.* 2010).

Reproduction and Population Structure Calves are born throughout the year in the wild (and in captivity, see Mentis 1972, Skinner *et al.* 2002), although there are certainly some seasons where more calves are dropped than others (Ansell 1960a, Allsopp 1971, Simpson 1974a, Plumptre 1991, Apio *et al.* 2009). In Kenya, there were peaks in births in Feb and Sep, just prior to the two main wet seasons when more nutritious forage was available (Allsopp 1971). In the Virunga Mts, births were more clumped from Jun–Sep, a drier period of the year in an environment where the cold rain can lead to mortality (Plumptre 1991). In Zambia, calves were recorded throughout the year (Wilson & Child 1964).

Gestation length is around 24–35 weeks with the average being around 25–26 weeks (Allsopp 1971, Dittrich 1972, Mentis 1972) and calves dropped weigh 3–4 kg. Usually one calf is born although occasionally twins occur. Calving intervals measured in captive animals are around 35–36 weeks and a ♀ can produce another calf within 48–54 weeks after the previous birth (Mentis 1972, Dittrich 1974, von Ketelhodt 1976a). Male calves develop horns about seven months after birth (von Ketelhodt 1976a) and ♂♂ develop the secondary sexual characteristics of a dorsal crest and darker pelage about two-and-a-half years after birth (Kingdon 1982). Males become sexually mature from about ten months of age, but do not take part in breeding until they are at least two years old (Mentis 1972). Females become sexually mature at 14–19 months (Dittrich 1972, Mentis 1972, Simpson 1974a, Allen-Rowlandson 1986). In Zimbabwe, the mean age at maturity was about 11 months in both sexes, coinciding (in ♂♂) with a combined testes weight of about 15 g (Morris & Hanks 1974).

Sex ratios at birth are equal, but adult ratios have varied from 45–115 ♂♂ to 100 ♀♀ in different sites (Wilson & Child 1964, Mentis 1972, Waser 1975a). Adult sex ratio obtained from a tsetse fly control area in Zambia was reported to be 80 ♂♂ to 100 ♀♀ (or 1 ♂ : 1.48 ♀; Wilson & Child 1964). Longevity in the wild has been reported at about 12–13 years (Mentis 1972); in captivity, maximum longevity has been recorded as 16 years and nine months for *T. s. sylvaticus* (Jones 1993).

Predators, Parasites and Diseases Leopards (Bushbuck are a significantly preferred prey, Hayward *et al.* 2006a), Lions *Panthera leo*, Spotted Hyenas *Crocuta crocuta*, Cheetahs *Acinonyx jubatus*, African Wild Dogs *Lycaon pictus*, Nile Crocodiles *Crocodylus niloticus* and African Rock Pythons *Python sebae* have all been recorded killing adults, and Robust Chimpanzees *Pan troglodytes*, baboons, Caracals *Caracal caracal* and several eagle species have been reported taking calves. African Golden Cats *Profelis aurata* also are probable predators (Kingdon 1982).

Zieger *et al.* (1998c) recorded a Bushbuck found dead on a ranch in Zambia with multiple superficial abscesses in the neck region, extensive granulomatous lesions in the lung, the bronchial and

mediastinal lymph nodes and several nodular lesions in the spleen. Histologically the lesions resembled those of tuberculosis, but mycobacteria could not be isolated. In Queen Elizabeth N. P., one reported case of rabies, a viral disease (Lyssavirus) that causes acute encephalitis was confirmed for Bushbuck (A. Apio & O. Bwangamoi pers. comm.).

Round (1968) provides a checklist of helminth parasites of the Bushbuck from all over Africa. The internal parasites of the Bushbuck have been relatively well investigated, particularly in southern Africa (e.g. Boomker & Kingsley 1984, Boomker *et al.* 1984, 1986), and Boomker *et al.* (1987) provided an updated list of all helminth parasites recorded from Bushbuck in South Africa at the time, including two species of cestodes (*Cysticercus* spp. and larvae of *Taenia* spp.) and 24 species of nematodes. Zieger *et al.* (1998a) recorded *Stilesia hepatica* from an animal in Zambia. Bwangamoi (1968), Woodford & Sachs (1973), Pullan *et al.* (1971) and Apio *et al.* (2006b) report on helminth parasites from Bushbuck in Uganda. Strongyle eggs recorded in faecal samples from Queen Elizabeth N. P. include *Oesophagostomum* spp., *Haemonchus* spp., *Bunostomum* spp. and the eggs of the cestodes *Moniezia benedini* and *M. expansa* (Apio 2003, Apio *et al.* 2006b). Generally, the prevalence of gastrointestinal tract parasites in Bushbuck from Queen Elizabeth N. P. is low. Apio *et al.* (2006c) tested the risk of infection with gastrointestinal parasites at different foraging height levels, and suggested that high browsing levels are responsible for low parasite infestations in Bushbuck. In the same park, Woodford (1976) reported on muscular and aberrant cysticercosis, which are conditions caused by larval stages of tapeworms infesting the musculature and connective tissues of their host. Sarcosporidiosis and larval pentastomidosis were also regularly found in the tissues of Bushbucks. Amongst the herbivores of Queen Elizabeth N. P., Bushbucks were the most commonly infested species (Woodford 1976). A filarial worm (*Setaria* sp.) was detected in blood samples of Bushbucks in the same study area. Apio & Wronski (2004) reported further on post-parturient changes in faecal helminth egg and coccidian oocyst counts of female Bushbucks in Queen Elizabeth N. P. *Eimeria* spp. was the most common coccidian infection, but did not lead to any clinical or pathological signs in the study population (Apio 2003). Apio *et al.* (2006b) investigated also seasonal, sexual and age-related variation in helminth egg and coccidian oocyst counts in the same population. The prevalence of *Moniezia* spp. and strongyle eggs was significantly higher during the wet season than during the dry season, and peak counts were recorded either during or soon after a peak rainfall. The same was true for *Eimeria* sp. Sexual and age-related differences in the prevalence of either parasite types were not found.

Other parasites recorded infesting Bushbucks include *Babesia* sp. (Bigalke *et al.* 1972) and the trematode *Schistosoma leiperi* (Malek & Ongom 1984). Trypanosomiasis, the nagana pest of cattle, is a condition commonly found in Bushbucks (Ferrante & Allison 1983, Moloo *et al.* 1995); the parasites (e.g. *Trypanosoma brucei*, *T. rhodesiae*) are transmitted by several *Glossina* spp. (tsetse flies).

In some areas, Bushbucks suffer heavy tick loads consisting predominantly of hard ticks (Ixodidae, De Castro & Newson 1984). The ixodid ticks of Bushbucks have been reported on by various authors (e.g. Dinnik *et al.* 1963, Woodford 1976, Terenius *et al.* 2000, Ntiamoa-Baidu *et al.* 2005), and Horak and co-workers (Horak *et al.* 1983c, 1989) determined actual tick and lice burdens of the species

in South Africa. Bushbucks have been infected with some tickborne diseases like bovine petechial fever (Davies 1993a), a rickettsial disease of cattle for which the Bushbuck is the reservoir host, as well as East Coast Fever, caused by a protozoan parasite regularly found in several tragelaphine species (Grootenhuis 1991).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Due to its widespread distribution, presence in numerous protected areas across its range, and its ability to survive around anthropogenically disturbed habitats, this species is not thought to be threatened. The Bushbuck's tendency to hide in dense cover has enabled it to survive in areas where hunting pressure is not too high (e.g. Parc National des Volcans in Rwanda; Plumptre *et al.* 1997). However, after larger-bodied species have been extirpated from an area, this species probably succumbs prior to the smaller-bodied species such as the duikers. Indeed, there are reports of Bushbuck being replaced by species such as Common Duiker *Sylvicapra grimmia* when human impacts (e.g. frequent burning, cattle grazing) are extensive (Kumanenge 1980). In areas where hunting pressure is severe, such as the Ankole Ranching Scheme around Lake Mburo N. P. in Uganda, the reduced competition from species that became less abundant outside the protected area (such as Bushbuck) may actually benefit other species, such as Common Duiker. Indeed, Common Duiker exhibited a significant change in habitat use around L. Mburo encroaching on the vegetation type otherwise normally used by Bushbuck (Averbeck *et al.* 2009a).

Most bushmeat research has been carried out in dense tropical forests where this species either does not occur or is not very common. Data from Rwanda show that Bushbuck meat is significantly lower in price than domestic meat and was the bushmeat most commonly purchased (Plumptre & Bizumuremyi 1996, Plumptre *et al.* 1997). In Sierra Leone (Kenema & Lalehun markets, respectively), Bushbuck meat accounts for about 2.5–6.6% of all traded animals and 3.1–23.5% of total biomass (Davies *et al.* 2007). The price for 1 kg of meat on a Ghanaian bushmeat market was reported as US\$2.63 and the distance travelled until it reached the consumer was 65 km (Cowlshaw *et al.* 2007). More research is needed on the savanna/forest-edge bushmeat trade in East and southern Africa to better understand how this species is affected by the trade.

Tragelaphus spekii SITATUNGA

Fr. Sitatunga; Ger. Sumpfantilope

Tragelaphus spekii Speke, 1863. Journal of the Discovery of the Source of the Nile, p. 223. Tanzania, Karagwe, E of L. Victoria, at a lake named 'Little Windermere' by Speke; identified as Bukoba district, L. Lwelo, 2° S, 30° 57' E by Moreau *et al.* (1946: 441).

Sitatunga *Tragelaphus spekii* gratus male.

Sitatunga *Tragelaphus spekii* gratus female.

Selous (1881) found the peoples of the lower Chobe and central Zambezi Rivers using the name 'sitatunga' (*sic*), the latter confirmed by Ansell (1978) who remarks that the Lozi and Tonga of Zambia use the name 'sitatunga'.

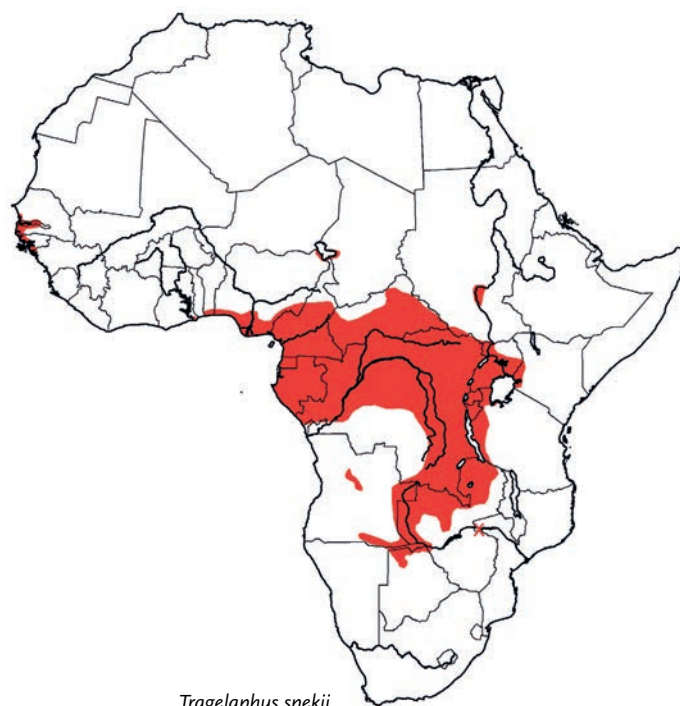

Taxonomy The scientific name has been given variously as *spekei* or *spekii* and the authority as Sclater or Speke. J. H. Speke described a young nzoé (the Kiswahili name for Sitatunga) in his Journal published in 1863 and stated in a footnote that the animal had been named by P. L. Sclater as *Tragelaphus spekii*. A year later Sclater published a description in a scientific journal under the heading *Tragelaphus spekei* sp. nov. Although Sclater's contemporaries clearly regarded him to be the authority, the rules of Zoological Nomenclature acknowledge the person who provided the first

description, and as this is clearly Speke, he is the authority and *spekii* (the genitive of the Latinized Spekius) is then the original and correct spelling (Grubb 2004).

As many as ten subspecies have been described, mainly based on hair texture, pelage colour and absence or presence of body stripes and spots. However, hair texture probably varies with climate, and pelage colour and presence of stripes and spots are highly variable even within the same population (some individuals are born with stripes and spots and others without). Furthermore, pelage colour darkens with age in some individuals, especially in older ♂♂, and stripes and spots fade with age, again especially in ♂♂ (E. Stokes pers. comm.). Sitatunga are probably monotypic, but until verified, at best only three subspecies, centred on different drainage systems, are provisionally retained (Kingdon 1982; and see Ansell [1972] who listed five). However, a

Lateral and palatal views of skull of Sitatunga *Tragelaphus spekii*.

Tragelaphus spekii

comparison of recent field descriptions spanning these basins (E. Stokes pers. comm., C. Thouless pers. obs., J. May & R. Lindholm pers. obs.) reveals that these three subspecies cannot be reliably distinguished on the oft-cited characteristics of pelage colour and pattern (see Geographic Variation). Synonyms: *albonotatus*, *anderessoni*, *baumii*, *gratus*, *inornatus*, *larkenii*, *selousi*, *speckeii*, *spekei*, *sylvestris*, *typicus*, *ugallae*, *wilhelmi*. Chromosome number: $2n = 30$ (Wurster & Benirschke 1968). Sitatungas have unusually large sex chromosomes, the X chromosome comprising 13% and the Y 7.3% of the haploid chromosomal complement in contrast to the mammalian norm of 5% (Wurster *et al.* 1968). Only one other member of the Bovidae, the Blackbuck *Antelope cervicapra*, has this peculiarity.

Description A medium-sized, swamp-dwelling antelope, exhibiting quite marked sexual dimorphism. The widely splayed, very long and narrow hooves (more than half the length of the foot) are unique. Adult ♂♂ have long pelage (4–7 cm), which is coarse to silky, dense or sparse, and uniform dark-chocolate brown, greyish-brown to grey. Top of the head and ears dark grey to dark brown, with a white chevron forward of the eyes; cheeks paler with one or two white spots, front of upper lips, chin and eyebrows white, inner ears with broad white margins. There is a white band across the throat and another across the chest. Body stripes and spots conspicuous, faint or absent. An inconspicuous, narrow, white stripe along the mid-line of the back is occasionally present. Tail dark brown at centre with white tip above, all white below. Legs same colour as body, sometimes darker at knee joint. Underside of feet naked. Adult ♀♀ similar to ♂♂, but smaller and less robust especially about the neck (see Measurements) and shoulders. The pelage is uniform bright to pale reddish-brown (usually), drab brown or rarely brownish-grey. Vertical white stripes across back, lateral stripe along flanks and white spots on thighs either conspicuous, faint or absent. Dark brown stripe usually along mid-line of back. White chevron forward of eyes usually less

distinct than in ♂ and sometimes absent. Calves woolly coated, more vibrant, but otherwise similar to ♀♀ in pelage colour and body stripes and spots. Females have two pairs of inguinal nipples.

Horns, present in ♂♂ only, are long and smooth, with spirals of up to two twists, almost triangular in cross-section, tips ivory-coloured, spread highly variable within populations.

Geographic Variation

T. s. spekii (Eastern or Northern Sitatunga) (includes *larkenii*, *ugallae* and *wilhelmi*): L. Victoria basin. Only faint shadow stripes on body of both sexes.

T. s. gratus (Western Sitatunga) (includes *albonotatus*): Congo Basin, West Africa and Sudan. Bold body stripes and spots in both sexes, but fading in adolescent ♂♂.

T. s. selousi (Southern or Zambezi Sitatunga) (includes *inornatus*): Bangweulu, Zambezi and Okavango basins. Body stripes and spots often present in ♀♀ and young, but absent in ♂♂.

Meinertzhagen (1916) erected the name *sylvestris* for Sitatungas on Nkose I. in the north-west corner of L. Victoria, which had stouter and stronger hooves than a population on a larger island nearby. Nkose I. is <1 km², dry, and densely forested to its edge, and separated from other Sitatunga populations by about 20 km of open water. Meinertzhagen's measurements plus a drawing of a hoof confirm that the Nkose I. Sitatungas clearly have wider feet than usual. However, to give this inbred, restricted population equal status to subspecies that range over thousands of kilometres seems hard to justify (Kingdon 1982).

Similar Species

Tragelaphus scriptus. Broadly sympatric. 'Hunched' appearance; short, wide and not splayed hooves; hairy lower feet. Inner upper forelegs white. Best identified by habitat and their habit of fleeing to dry ground when disturbed.

T. eurycerus. Sympatric through much of West and Central Africa, but in the forest – savanna ecotone. Large size; short, wide and not splayed hooves, and hairy lower feet. Legs banded black and white.

T. angasii. Allopatric, occurring in dense thickets and thicket woodland in south-east Africa from Malawi to South Africa. Short, wide and not splayed hooves, and hairy lower feet. Males with distinct fringe of long hair hanging down from under chin, down neck and along sides of belly to between hindlegs.

Distribution Endemic to Africa. Confined to the wetlands of the central latitudes between 13.5°N and 20°S. Sitatungas have a disjunct distribution, centred on the wet regions of central African forests and savannas.

Historical Distribution Widespread in wetlands throughout the central latitudes of Africa, from SW Senegal to W Guinea, and then from SE Ghana to W Kenya and from L. Chad and S Sudan to the Okavango Delta in Botswana. They probably once occurred throughout the lowland forest zone of Sierra Leone, Liberia and Côte d'Ivoire, but there are no confirmed records between Guinea and the Volta R. (Sidney 1965, Grubb *et al.* 1998).

Current Distribution Probably much the same as historical geographical range although there has been some reduction in area of occupancy. Where there has been loss or modification of the Sitatunga's habitat as a result of human population pressure, extinctions have occurred, such as in Togo (where they may have survived in small numbers on the Mo-Kaitcha Rivers in C Togo into the late 1980s; East 1999), or numbers are greatly reduced. Given the highly cryptic nature of Sitatungas and inaccessibility of their habitat, the extent of the loss is difficult to verify. Their secretive behaviour means that Sitatungas can survive in close proximity to human habitation, as long as some of their habitat remains: they have been observed from the air, feeding 10–20 m from villages, separated only by a narrow strip of dense papyrus (J. May & R. Lindholm pers. obs.).

Sitatungas are widespread and locally common in central African forests (SE Cameroon, Gabon, SW Central African Republic, Congo and DR Congo) and swamps within savannas of south-central (Zambia), East (Rwanda, Burundi, SW Uganda, NW Tanzania) and southern Africa (N Botswana). Sitatungas are also recorded in the Zambezi R. in extreme NW Zimbabwe, and an isolated population may still persist in western Tete Province in Mozambique (East 1999). They are not uncommon throughout coastal wetland areas of West Africa (Senegal, Gambia, SE Ghana and Nigeria), although at much lower population levels compared with those in central Africa (J. Mason pers. comm.). East (1999) reported that Sitatungas are now extinct in Niger, where they once occurred in the south-east around L. Chad. However, Sitatungas are still seen in the eastern and southern parts of L. Chad, during the most recent aerial surveys aiming at counting waterfowl in Lake Chad Basin (January 2008), Trollet *et al.* (2008) observed 13 individuals (10 males and 3 females)

Habitat Tall and dense vegetation of perennial and seasonal swamps, marshy clearings within forests, riverine thickets and both brackish (Galat-Luong & Galat 2002) and freshwater mangrove swamps. Within savanna environments, Sitatungas are typically found in extensive monospecific stands of papyrus *Cyperus papyrus*

and the reeds *Phragmites* spp. and *Echinochloa pyramidalis*, or a mosaic of all three species, often interspersed with bullrush *Typha* spp., sedges *Cyperus* spp., pampas grass *Miscanthus junceus*, hippo grass *Vossia cuspidata* and short grass clearings (e.g. *Acroceras macrum*, *Panicum repens* and *P. parvifolium*). They occur only on soft, moist to wet substrates, where vegetation provides adequate camouflage and density is sufficient to hinder predators. They favour extensive areas of swamps more than 1 km wide, although they do occur in relatively narrow patches of less than 50 m and in tall, dense grass of wet dambos adjacent to deep streams. Sitatungas commonly occur on floating mats of vegetation, particularly papyrus sudd, where underlying water depth may be up to 4 m; also on rooted vegetation in water depths up to ca. 1 m. They visit swamp margins, where sedges and grass growing on moist substrate meet dry flood-plains or gallery forest. Within seasonally flooded forests, Sitatungas occur in marshy clearings ca. 20–30 ha in diameter of mainly short sedges and grasses (Magliocca *et al.* 2002). In areas free of predators they may occur on dry terrain (such as Nkose and Rubondo Is. in L. Victoria).

Sitatungas usually avoid open water devoid of vegetation. They require dry resting areas on floating vegetation, thick vegetation that can be trampled to form a mat above water, or small dry patches of ground within swamp (J. May & R. Lindholm pers. obs.). They readily disperse into sedge and grass flood-plains during the wet season, if depth of water and density of vegetation provide sufficient cover, especially where small 'termitaria islands' ca. 25 m diameter are common (J. May & R. Lindholm pers. obs.).

Abundance Sitatungas are under-reported and are more common than sightings indicate. Their cryptic nature and the relative inaccessibility of their habitat have, until recently, hindered reliable estimates of abundance. For eastern and southern savanna swamps estimates vary widely, but are probably a function of survey technique and timing and frequency of observations rather than a true difference in density. Early estimates, which are crude and conservative, include an average of 44 visible Sitatungas in the tiny 2 km² Saiwa Swamp, Kenya (Owen 1970); at least 10–15/km² or 18,000–27,000 in Bangweulu Swamps, Zambia, total range ca. 2000 km² (Manning 1975); 0.3–1.3/km² or 234 in the Panhandle of the Okavango, Botswana, which has about 1000 km² of permanent swamp (Games 1983a); and 0.5/km² or about 4000 for the whole Okavango Delta, which includes some 8000 km² of permanent swamp (Ross 1992). Recent surveys from low-flying aircraft have produced more realistic densities, of up to 64/km² with 5700–9900 in Akagera N. P., Rwanda (Beudels *et al.* 1992b, Beudels-Jamar *et al.* 1997) and up to 60/km² with about 1000 in the Busanga Swamps (total range ca. 18 km²), Zambia, the latter supported by mark-recapture estimates (J. May & R. Lindholm pers. obs.).

There are only limited estimates of abundance in the forest habitats of West and central Africa. In the Congo rainforests, the Mbeli Bai (0.13 km²) in Nouabale-Ndoki N. P. supports 10–12 animals or 92/km² (E. Stokes pers. comm.). The slightly larger Maya Nord clearing (0.2 km²) in Odzala N. P. supports 30–36 animals or 180/km². Since there are about 100 clearings (Magliocca *et al.* 2002), or about 20 km² of Sitatunga habitat, a rough abundance for Odzala N. P. could be about 3000–4000 Sitatungas.

East (1999) estimated a total population size for Sitatungas of 170,000, but this was based on a general 'area of occupancy' of

1,230,000 km², which includes vast areas of unsuitable habitat rather than occupied range. The occupied range of Sitatungas includes a diversity of habitats from vast papyrus and reed swamps in savanna to small swampy clearings in wet forests and each type of habitat can be expected to support different densities. Even within specific habitats some parts will support significantly more Sitatungas than others (Beudels *et al.* 1992b, J. May & R. Lindholm pers. obs.). Unfortunately, the extent of the occupied range is unknown and given the extreme variation in densities the overall total abundance of Sitatungas cannot be reliably estimated.

Adaptations Sitatungas are adapted to fully exploit the swamp niche. They are the only large mammal that both lives and feeds in deep water and the only one to consume large quantities of papyrus and so utilize the high productivity of tropical swamps. Their unique long and splayed hooves with their rubbery water repellent-like coating provide purchase over slippery, muddy substrates and mats of floating vegetation; a wedge-shaped profile, combined with the lowering of the head, and in ♂♂ the laying of the horns on the back, facilitate movement through dense and tangled vegetation. Slow and deliberate movement makes them difficult to see and, combined with their toe-pointing gait, allows almost silent passage through water (Williamson 1986). To escape detection, they may 'freeze' in action, their colour providing perfect camouflage. When flushed, Sitatungas move towards flooded areas where their plunging run is very efficient through shallow water and clumped vegetation. They are awkward on dry ground and highly vulnerable to predators there. They use pathways to move efficiently between resting and feeding grounds, but rarely when fleeing an intruder, as they can move through the dense vegetation of the swamp swifter than any other large mammal.

Sitatungas are good swimmers and are often in water up to their backs but rarely enter water devoid of profuse vegetation, thereby avoiding crocodiles. In extreme circumstances (for example, when troubled by flies and bees or when pursued) some will submerge themselves fully with only the nose breaking the surface. Sitatungas often sun themselves after a bout of feeding in water. To this end they trample thick vegetation in a turning motion, to make a dry platform above a water-logged environment, or a grassy bed on dry-ground.

Hearing is acute and directional; their swivelling, saucer-shaped ears allow Sitatungas to pinpoint exactly where a sound originates, an important skill in dense vegetation where long sight is of little benefit.

Foraging and Food Sitatungas are selective mixed feeders taking a range of grasses, sedges and browse. Sitatunga select for new grass shoots and newly emerged leaves, new shoot tips and flowering spikes of sedges, the base of young shoots of *Typha*, new shoot tips and new foliage of herbs, shrubs and tree saplings as well as flowers and fallen fruits (Owen 1970, Games 1983b, J. May & R. Lindholm pers. obs.). In studies involving stable carbon isotope analysis of animals in both East and southern Africa, Sitatungas in East Africa (where samples came from the Ituri Forest and Garamba N. P.) had no grass in their diet, while animals in southern Africa had a diet of about 34% grass. However, these differences do not necessarily relate to regional differences in the consumption of grass or browse, since Sitatungas have regular access to both food sources (Cerling *et al.* 2003, Sponheimer *et al.* 2003b).

Bullrushes (*Typha* spp.), sedges (*Cyperus* spp.), aquatic grasses such as *Vossia*, *Echinochloa*, *Pennisetum*, *Leersia*, *Acroceras*, *Panicum* and species in the families Umbelliferae and Acanthaceae in Saiwa or Leguminosae in Bangweulu and Busanga, are the most common plants eaten. The first three are usually abundant and form the bulk of the Sitatunga's diet. However, others that are sparsely distributed are often sought after, such as *Hydrocotyle ranunculoides* and *Oenanthe palustris* (Umbelliferae), *Hygrophila spiciformis* (Acanthaceae), *Aeschynomene* spp. (Leguminosae), *Persicaria* spp. (Polygonaceae) and *Amaranthus* spp. (Amaranthaceae) (Owen 1970, J. May & R. Lindholm pers. obs.). *Cyperus papyrus* and *V. cuspidata* form the bulk of food in the Okavango Panhandle (Games 1983b), but neither occurs in Saiwa where *Typha* and *Pycnus* are commonly eaten (Owen 1970). Major food items in Busanga are *Typha*, *Cyperus* spp. and *V. cuspidata*, the latter two also commonly eaten in Bangweulu (J. May & R. Lindholm pers. obs.).

Seasonal changes in diet occur in those swamps that experience a significant rise in water level. Temporarily flooded areas give access to new growth of sedges, aquatic grasses, flood-plain and termitaria herbs and in some cases the forest edge, providing access to trees such as *Acacia nigrescens*, *Diospyros mespiliformis* and dry-ground herbs.

Sitatungas mostly forage in water up to their knees or belly and often browse on floating vegetation in water up to their backs. Within the savanna environment they start feeding at dawn and may move to a clearing, the swamp interface, or during the wet season, the termitaria edge or flood-plain from ca. 07:00h, usually returning to the swamp or termitaria centre after about 1–2 hours in the open. Bouts of feeding continue to alternate with resting and ruminating. They may emerge into the open again at dusk and again feed until satiated around 20:30h. There may be a short period of activity around midnight (J. May & R. Lindholm pers. obs.). Within the seasonally flooded forests most individuals remain permanently in the swampy clearings during the day, spending 27% of their time feeding and some move into the forest at night, especially as more of the clearing floods (Magliocca *et al.* 2002, 2003). On a daily basis Sitatungas are sedentary, an individual usually only traversing a small area up to around 250 m wide while foraging, the average distance travelled being ca. 25 m/h (J. May & R. Lindholm pers. obs.).

To reach favoured plant parts, Sitatungas may stand up on their hindlegs like the Gerenuk *Litocranius walleri*, or flatten or bend the plant with a hoof or horns (J. May & R. Lindholm pers. obs.). In the Maya Nord clearing, where Sitatungas have year-round access to mineral-rich sedges (Cyperaceae) and grasses, ♀♀ also spend ca. 20% and ♂♂ ca. 50% of their feeding time foraging in elephant dung for the seeds of *Strombosia pustulata* and *Strychnos camptoneura* (Magliocca *et al.* 2003). Sitatungas will immerse their heads and necks in deep water to reach these seeds and use their muzzles to break open the dung and select the larger seeds.

Social and Reproductive Behaviour Sitatungas are more sociable than is generally supposed. Of more than 2000 observations of Sitatungas from the air in the Busanga swamps, over half of all animals were within sight (less than ca. 10 m) of one or occasionally two others and sometimes up to seven others. The spacing of these 'groups' can be very close and these most likely form parts of larger associations (J. May & R. Lindholm pers. obs.). In Saiwa, where only parts of groups were visible, over half of the 359 observations were of groups of two or more Sitatungas (Owen 1970), while in the

Sitatunga *Tragelaphus speikii*.

marshy clearings of the Congo group size varied from 16 to 36 over ca. four years in Maya Nord (Magliocca *et al.* 2002) and averaged 10–12 in Mbeli Bai (E. Stokes, pers. comm.).

Females generally associate with ♀♀, and ♂♂ generally with other ♂♂; 75% of ♀♀ and 70% of ♂♂ in Busanga were either alone or with only the same sex (J. May & R. Lindholm pers. obs.). Around 59% of ♀♀ were either alone or only with other ♀♀ in Saiwa, although ♂♂ rarely associated only with ♂♂ probably because of the low number of ♂♂ (Owen 1970); 82% of resting groups in Maya Nord were female-only subgroups consisting of adults and subadults with or without young, and 4% male-only, the latter influenced by the low number of ♂♂ (Magliocca *et al.* 2002). In Maya Nord, the mother–offspring subgroup was the most stable and, while other subgroups fluctuated on a daily basis, many

of the female subgroups often included the same members indicating preferential social affinities (Magliocca *et al.* 2002).

In Busanga, home-ranges both within and between sexes overlap extensively and are seasonal (J. May & R. Lindholm pers. obs.). Individuals use the same centres of activity in consecutive years. Dry season home-ranges are always within permanent swamp and are occupied from about May to Jan (mean = ca. 190 ha, range ca. 9–1180 ha, $n = 31$). Some individuals have only one centre of activity during the dry season, others range widely between two or three areas ca. 5 km apart. The considerable variation between individuals is apparently not related to either sex or age. Dispersal to wet season ranges begins mid- to end Jan, when the plains begin to flood. Most move out of the swamp onto the flooded plains and the distance travelled from their dry season range varies, usually 2–5 km but some less than

1 km and rarely up to 12 km. There is only one centre of activity in the wet season (mean = ca. 60 ha, $n = 32$) that the individual occupies until about May when the flood-plain becomes too dry. In Bangweulu, home-ranges also overlap extensively (mean = 32 ha, $n = 9$) but apparently expand only very slightly during the wet season (Manning 1983). During the wet season, Situngas inhabiting the permanent river swamp in Bangweulu move into the seasonally flooded sedge marsh (Manning 1983), at least some Situngas move onto flood-plains in the Okavango (Games 1983b, Ross 1992) and some ♂♂ are reported to wander away from the swamp in Uganda and Tanzania (Kingdon 1982). In Maya Nord clearing, the core group remain all year round (Magliocca *et al.* 2002) while in Mbeli Bai Situnga visits drop in the dry season indicating that at least some individuals may undergo seasonal movements (E. Stokes pers. comm.).

Situngas are polygamous. A dominant ♂ forms a 'tending bond' with an oestrous ♀ for 1–2 days, testing her urine and keeping other ♂♂ away until she is ready to mate. While ♂♂ are usually not territorial, there is evidence in the Busanga that some establish temporary territories for part of the wet season (J. May & R. Lindholm pers. obs.). Occasionally, serious fights between two prime ♂♂ occur on termitaria, with the winner chasing the other off for at least 100 m, then returning to 'patrol' his area, running around its perimeter and occasionally ploughing the ground with his horns. Combats resulting in fatalities have been reported (Selous 1881, Starin 2000, Breuer & Hockemba 2008). In Maya Nord, the resident group apparently functioned as a harem, with the same adult ♂, the stouter of the two present, monopolizing all ♀♀ for at least 44 months (Magliocca *et al.* 2002). All ♂♂ born within the clearing were driven off by this ♂ and the subordinate adult eventually emigrated (Magliocca *et al.* 2002). In Mbeli, intermittent fighting for 90 min followed by an intensive battle of 30 min between two adult ♂♂ culminated in the death of one and the winner becoming the dominant ♂ visiting the bai over the following three years (Breuer & Hockemba 2008).

Calves hide alone for about the first seven weeks in Abuko N. R., Gambia (Starin 2000) and about two weeks in Maya Nord (Magliocca *et al.* 2002), except for brief bouts of suckling. After this 'lying out' phase the calf closely follows its mother and will remain with her even after the next calf is born (Owen 1970, Starin 2000), the mother and very young calf rarely associating with others (J. May & R. Lindholm pers. obs.).

The behaviour of Situnga has been studied in captivity (Walther 1964a), but rarely recorded in the wild. In Maya Nord, time devoted to social behaviour is surprisingly low, Magliocca *et al.* (2002) recording less than 1% of daytime observations. Various postures, mostly involving the head and neck, communicate 'status'. The following are most likely to be seen in the wild: when Situngas meet they touch noses first and sometimes examine each other's anogenital area; social licking and nibbling often follows. When alert the head is up, the neck curved and ears swivelling; if the animal is alarmed the head is raised as high as possible, and if startled animals may freeze in action, often with one leg raised. The head is lowered and the neck extended when the animal is investigating a suspicious object, such as a crocodile. Threat displays include feinted attacks, where the animal jumps forward raising the forelegs while the hindlegs remain planted, and ♂♂ frequently horn the ground or bushes. Feinted attacks are also seen in running games where individuals run and caper about, usually alone. Fighting in the ♂♂ involves combatants, with horns engaged at bases, trying to push each other backwards (J. May & R. Lindholm pers. obs.).

Situngas occasionally emit one to several coughing-barks, usually at night (Owen 1970). Sometimes the barking of one individual may be taken up serially by others, up and down the swamp (Owen 1970, J. Kingdon pers. comm.). Females bark when chasing off other ♀♀ (Magliocca *et al.* 2002). A low-pitched squeak is uttered amongst feeding Situngas and the calf's call to its mother is a sheep-like bleat (Owen 1970). In captivity, a sheep-like bawl is heard when moving, particularly during running and jumping games (Walther 1964a) and a similar sound is often emitted when Situngas are captured in the wild (Manning 1983, J. May & R. Lindholm pers. obs.). In captivity, ♂♂ emit a suppressed bellow while following a ♀ during the mating ceremony or approaching a herd of ♀♀ (Walther 1964a).

Situngas occasionally feed or lay down close to small groups of Southern Lechwes *Kobus leche* but do not intermingle. Calves playfully chase off Spur-winged Geese *Plectropterus gambensis*, as do ♂♂ occasionally (J. May & R. Lindholm pers. obs.). Situngas tolerate Yellow-billed Oxpeckers *Buphagus africanus* and African Jacanas *Actophilornis africanus* perching on their backs and Great Egrets *Casmerodius albus* grooming their ears and genital-perianal areas for arthropods (Ruggiero & Eves 1998); Maisels (2003) recorded White-tailed Alethes *Alethe diademata* and a bulbul (Pycnonotidae) gleaning ectoparasites from a Situnga. They are wary of crocodiles, but will continue to feed close to them when out of water, keeping them carefully in sight.

Reproduction and Population Structure Situngas give birth throughout the year (Owen 1970, Magliocca *et al.* 2002, J. May & R. Lindholm pers. obs.); however, there are reports of a peak in the dry season for Caprivi, Namibia (Davison 1950) and in wetter months for Saiwa (Owen 1970), although the evidence is weak.

Estimates of gestation vary, from 27–34 weeks in captive ♀♀ (Manning 1983) to as little as 24 weeks in Maya Nord ($n = 1$, Magliocca *et al.* 2002). Single calves, weighing ca. 5 kg (Manning 1983) are born at intervals ranging from 8.5–12 months in Abuko N. R. ($n = 3$, Starin 2000) to 5.5–9.0 months in Maya Nord ($n = 6$, Magliocca *et al.* 2002); the shorter period in the latter possibly related to the extraordinary high quality of food available. Calves are suckled until about four months old (Magliocca *et al.* 2002). They suckle for 2–21 min in captivity ($n = 52$; Walther 1964a). Females are sexually mature at 24–30 months in Maya Nord ($n = 3$, Magliocca *et al.* 2002), 14–23 months in captivity (Manning 1983), and in Busanga one young ♀ of ca. 16 months and only 60% of mean adult body weight was pregnant. Age at first birth in Mbeli is 2.8 years ($n = 2$, E. Stokes & T. Breuer pers. comm.). In captivity, ♂♂ are sexually mature at ca. 18 months although unlikely to mate in the wild until approaching their maximum weight at six years (Manning 1983).

In Maya Nord, all nine adults gave birth to at least one young in one year, and at least 78% did so in another (Magliocca *et al.* 2002). In Mbeli, one ♀ gave birth ten times in ten years (E. Stokes & T. Breuer pers. comm.) and the single ♀ in Abuko N. R. gave birth four times in four years (Starin 2000); and in Busanga 70% of ♀♀ examined were pregnant and 20% were lactating (J. May & R. Lindholm pers. obs.). The birth rate in Mbeli was 0.79 (births/♀/year $n = 31$; E. Stokes & T. Breuer pers. comm.).

More ♀♀ (60–75%) than ♂♂ are seen (Owen 1970, Manning 1983, Magliocca *et al.* 2002, J. May & R. Lindholm pers. obs.). Given the extended 'lying out' phase of calves, their much lower visibility in dense vegetation, and the difficulty of distinguishing young from adult

♀ ♀, the proportions of young to adults observed are crude, ranging from 10 to 36% (Owen 1970, Games 1983a, Manning 1983, J. May & R. Lindholm pers. obs.). In Maya Nord, where the whole group was visible, on average 34% were young ($n = 16\text{--}36$, Magliocca *et al.* 2002).

Mortality rates in good-quality habitat in Busanga were low with only 10% of 20 collared Sitatungas dying, equating to an annual survival rate of 0.94; but in marginal habitat mortality rates were very high, 58% of 12 collared animals dying, the annual survival rate being 0.76, many being killed by Lions *Panthera leo* shortly after fires (J. May & R. Lindholm pers. obs.). In rainforest clearings, the survival rate of calves is very high. In Maya Nord, 80% of young less than five months ($n = 10$, Magliocca *et al.* 2002), and in Mbeli 76% of young less than six months survive ($n = 28$, E. Stokes & T. Breuer pers. comm.). In captivity, Sitatungas live to at least 21–22 years (Jones 1993, Weigl 2005), and in the wild to at least 11 years (Manning 1983).

Predators, Parasites and Diseases Nile Crocodiles *Crocodylus niloticus*, Lions, Leopards *P. pardus*, African Wild Dogs *Lycaon pictus* (Games 1983a) and African Rock Pythons *Python sebae* (E. Stokes & T. Breuer pers. comm.) are known predators, and Spotted Hyenas *Crocuta crocuta* and jackals *Canis* spp. probably also prey on Sitatungas.

Sitatungas host the protozoans *Trypanosoma congolense*, *T. vivax* and *T. brucei*, all three causing ngana (trypanosomosis) in cattle, and two subspecies of the latter, *T. b. rhodesiense* and *T. b. gambiense*, are the agents of sleeping sickness (trypanosomosis) in humans. Although Sitatungas were implicated in the Uganda sleeping sickness epidemic in the early 1900s, recent evidence suggests that the main causative agent was *T. b. rhodesiense*, a zoonosis with a principally domestic cattle reservoir, and that movement of cattle during livestock restocking at the end of the rinderpest pandemic was most likely the cause (Fèvre *et al.* 2004). The riverine tsetse fly *Glossina palpalis*, an important vector of African trypanosomes, feed on Sitatungas in S Cameroon (Njiokou *et al.* 2004a).

Sitatungas are also susceptible to rinderpest caused by the virus *Morbillivirus* (Shanthikumar & Atilola 1990), while captive animals have shown susceptibility to bovine tuberculosis, a chronic disease in domestic ruminants caused by the bacterium *Mycobacterium bovis* (Pavlik *et al.* 2002), heartwater caused by the rickettsial agent *Ehrlichia ruminantium* (Okoh *et al.* 1986), and to malignant catarrhal fever (Barnard *et al.* 1994, Flach *et al.* 2002). Sitatungas would be vulnerable to all four diseases in areas where cattle invade flood-plains such as the Okavango panhandle (Games 1983b).

Two new species of flukes have been described from Sitatungas: the liver fluke *Fasciola tragalaphi* from Chobe Swamps (Pike & Condry 1966) and later found in Ugandan Sitatungas (Pullan *et al.* 1971); and the bilharzia fluke *Schistosoma leiperi*, from Zambia (Le Roux 1955). The latter species is one of the many schistosomes causing bovine schistosomiasis. A *Stomoxys* fly outbreak in Congo caused adult ♂♂ to lose condition over several weeks in the Mbeli clearing and finally disappear, presumed dead (Huchzermeyer *et al.* 2001, Elkan *et al.* 2009).

Sitatungas are known to host the ticks *Rhipicephalus compositus*, *R. aquatilis* and *Haemaphysalis aciculifer* (Manning 1983, Walker *et al.* 1993) and the amphistome *Carmyrius spatiosus* (Pike & Condry 1966).

Conservation IUCN Category: Least Concern. CITES: Appendix III (Ghana).

Loss of habitat is the main threat to the future persistence of the species. In the past it was most likely that Sitatungas were able to

move along drainage lines during wet seasons, facilitating exchange between populations. However, with the ever-increasing loss of wetlands throughout their range, these routes of dispersal are being cut and many populations are becoming isolated. Sitatungas are highly vulnerable to long-term changes in water level because it alters vegetation structure, which in turn largely determines their distribution and abundance (Beudels-Jamar *et al.* 1997); both lower and higher water levels make them more accessible to hunters and predators.

Surprisingly, perhaps, swamps are extremely vulnerable to fire; up to 75% of the Okavango (Games 1983a) and vast areas of Bangweulu and Busanga (J. May & R. Lindholm pers. obs.) are burnt each year. Hunting has probably not had a significant effect in the past because of the inaccessibility of their habitat, but with fragmentation of swamps, increasing human population and modern technology this is changing. Hunting for bushmeat throughout West Africa is now a major threat (J. Mason pers. comm.).

Over the long term, only those populations living in extensive swamps that are relatively isolated can be considered secure. Major populations occur in areas of low human density, for example Dja Wildlife Reserve and Lobeke N. P. (Cameroon), Bangassou F. R. (Central African Republic), Odzala N. P. and Nouabale-Ndoki N. P. (Congo), Salongo N. P. (DR Congo), Bangweulu and Busanga Swamps (Zambia), Okavango Delta (Botswana) and Akagera N. P. (Rwanda) (East 1999). A population also occurs on Rubondo I., which is a National Park (Tanzania) (East 2002). However, very few large populations are to be found within genuinely protected areas and the extensive swamps such as the Okavango and Bangweulu, which can be expected to provide the most secure habitat in the long term, generally have no special protection status. To secure the long-term survival of Sitatungas, a system of stable protected areas is needed, each of a size resilient to burning. These areas must contain permanent swamps together with the adjacent seasonal swamps, flood-plains and associated gallery forest. Fire management is essential.

Measurements

Tragalaphus spekkii

T. s. selousi

HB (♂♂): 1610 (1360–1770) mm, $n = 30$

HB (♀♀): 1320 (1040–1460) mm, $n = 91$

T (♂♂): 300 (140–350) mm, $n = 24$

T (♀♀): 250 (170–370) mm, $n = 92$

E (♂♂): 140 (120–170) mm, $n = 21$

E (♀♀): 120 (110–140) mm, $n = 81$

Tragelaphus eurycerus BONGO

Fr. Bongo; Ger. Bongo

Tragelaphus eurycerus (Ogilby, 1837). Proc. Zool. Soc. Lond. 1836: 120. West Africa [1837]. 'Their origin is unknown, but I have reason to believe they [the syntypes] came from Western Africa.'

Mountain Bongo *Tragelaphus eurycerus isaaci* male.

Taxonomy Historically, classification of this species has been problematic. Originally described as *Antelope eurycerus*, it was subsequently included in the genus *Tragelaphus* by Lesson (1842). Later it was shifted to a new genus, *Boocercus*, and then to *Taurotragus* (Thomas 1902, Simpson 1945, Haltenorth 1963). Most recent authors include the species in the genus *Tragelaphus*, sometimes in the subgenus *Boocercus* (Ansell 1972, Van Gelder 1977a, Ralls 1978, Grubb 2005). The shifts in nomenclature were due to confusion about key morphological characteristics. The Bongo has two characteristics that are more similar to the elands (sometimes placed in the genus *Taurotragus*) than other members of the genus *Tragelaphus*, namely the presence of horns in both sexes and the ox-like tail. However, the Bongo's open 'one-twist' spiral horns, the lack of a dewlap and non-ox-like feet are similar to other members included in *Tragelaphus* (see Ansell 1972). The name *euryceros* Gray, 1850, sometimes used for the species name, is an incorrect subsequent spelling (see Grubb 2004, 2005).

Up to five subspecies were previously described, but only two are presently recognized: *T. e. eurycerus* and *T. e. isaaci* (Kingdon 1997,

East 1999). Analysis of genetic characters will help elucidate the status of subspecies in *Tragelaphus eurycerus*. Synonyms: *albovirgatus*, *cooperi*, *euryceros*, *isaaci*, *katanganus*. Chromosome number: $2n = 33$ in ♂ (translocated Y) and 34 in ♀ (Wurster 1972, Wallace 1978a, Benirschke *et al.* 1982).

Description Large, reddish-brown, heavy-bodied antelope with white and black markings and long spiral horns. Lower jaw dark, upper crossed by a white chevron. Underside of the chin is white, the throat black with 1–2 variable white markings on rear cheek. Pelage around eyes lighter, ears large spreading outwards with white-and-black-fringed markings. Pelage light brown to dark maroon, with 9–15 thin, vertical, white stripes running from the dorsal ridge to the belly, and extending from the shoulder to the hindquarters. Hair short (1–2 cm) over much of body, longer at throat. Dorsal crest brown and white (3–4 cm) extending from withers, along back, to base of tail. Chest crossed by white marking at base, legs marked with dark and white from elbow to fetlock. There is no dewlap. Tail (ca. 25% of HB) is brown, ending in a black tuft. Facial, pedal

Lateral and palatal views of skull of Bongo *Tragelaphus eurycerus*.

and inguinal glands absent. Colouration similar in ♂♂ and ♀♀, but there is pronounced dimorphism in body size. Females have two pairs of nipples.

With the exception of the elands, this is the only other member of the genus *Tragelaphus* with horns present in both sexes. Horns are long and dark with white-yellowish tips curving up and backward in an open spiral. Horns of ♂♂ are thicker and have a wider spread than ♀♀.

Geographic Variation

T. e. eurycerus (Lowland or Western Bongo): patchily distributed across the lowland forest and savanna-forest transition areas of West and central Africa. Generally smaller than Mountain Bongo, and adult ♂♂ tend not to darken with age.

T. e. isaaci (Mountain or Eastern Bongo): mountain forests of Kenya. Taller, heavier and longer-legged, with head and neck of older ♂♂ a dark chocolate-brown in colour.

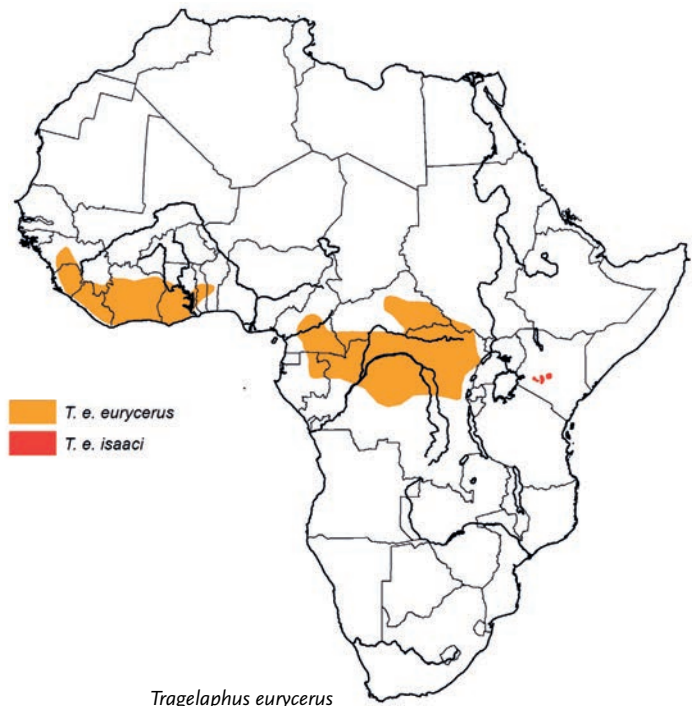

Similar Species

Tragelaphus scriptus. Broadly sympatric. Substantially smaller (24–80 kg). Shorter horns on ♂♂ with tighter spiral.

T. spekii. Smaller, with longer hooves and shaggier pelage. Restricted to swamps and swamp-forest and largely absent from West Africa, west of the Volta R.

Distribution Endemic to Africa, associated with disturbed forest areas and the forest–savanna ecotone in the lowlands of West and central Africa and the Kenya highlands (East 1999).

Historical Distribution In West Africa, the Lowland Bongo occurred from SW Guinea and Sierra Leone to Benin, but was absent east of the Dahomey Gap to Cameroon. The central African populations ranged from S Cameroon along the lowland forest zone to E DR Congo and S Sudan (Ralls 1978). Historically, the Mountain Bongo occurred in and around forested zones of Mt Kenya, the Aberdares, Mau forest, Cherangani hills and Chepalungu hills in Kenya and Mt Elgon in Kenya and Uganda (Kingdon 1982, East 1999). Reports of Bongos from SW Ethiopia and N Tanzania have not been confirmed (Ansell 1972).

Tragelaphus eurycerus

Current Distribution The West Africa populations of Lowland Bongo are declining throughout much of their range in Guinea, Sierra Leone, Liberia, Côte d'Ivoire, Ghana and Togo (where they now probably only occur in Fazao N. P.); a few Bongos may still exist in the Mt Kouffe area of Benin. Most of the central Africa populations of Lowland Bongo still maintain their historical distribution extending from just north of the Sanaga R. in Cameroon and from NE Gabon east to Congo, Central African Republic, DR Congo and SW Sudan (East 1999).

Some sources note that Bongos occur only east of the Sanaga R. (e.g. Ralls 1978), but they are definitely recorded from Mbam Djerem, north of the river (Maisels *et al.* 2000), suggesting that the forest–savanna transition zone, east of the Adamawa highlands, is their northerly limit in Cameroon. Reports of Bongos in Campo-Ma'an N. P., well to the west of their known distribution in Cameroon (see East 1999), have not been verified during intensive field surveys (Matthews & Matthews 2003). Although the Ivindo R. was taken to be the southern limit of distribution in Gabon, there is a camera-trap record of the species from south of this river in Ivindo N. P. (P. Henschel pers. comm.). There is also an unsubstantiated record from Mt Fouari in the Niari region in the south-west of the Congo (Hecketsweiler 1988); however, recent surveys have failed to record the species here, and they certainly no longer occur, if they ever did.

The distribution of the Mountain Bongo has been reduced to four small, completely isolated populations in patches of forest on Mt Kenya, the Mau and Eburu forests, and the Aberdares in Kenya. It was extirpated from Uganda (Mt Elgon) around 1913–14 (Kingdon 1982, East 1999).

Habitat The Bongo is described as an ecotone species, thriving on transition vegetation at the forest edge and in new-growth areas that occur after disturbance (i.e. post-timber exploitation, elephant disturbance, tree-falls, landslides, burned fields) (Kingdon 1982, Elkan 2003). Bongos in the savanna–forest transition zone in SW

Sudan move during the wet season to rich food patches that are often a considerable distance from forested areas and retreat in the dry season to dense forest in search of food (Hillman 1986b). Similarly, in the Aberdares Bongos have been recorded moving in the wet season (Apr–May and Sep–Dec) to lower altitudes (below 2500 m) where secondary growth has invaded formerly cultivated areas, and in the dry season (Jan–Mar and Jun–Aug) move back up to the upper reaches of montane forest and *Hagenia/Podocarpus* cloud forest and bamboo thickets over 3000 m (Edmond-Blanc 1960, Kingdon 1982); however, recent wet-season observations from the Aberdares indicate that Bongos are not necessarily moving to formerly cultivated areas only, but are now primarily found along valleys where an abundant herbaceous layer (of preferred browse species) underlies tall, semi-open forest (L. Estes pers. comm.). Young & Evans (1993) discuss a possible record from 4300 m on Mt Kenya.

Forest clearings and mineral licks are important for geophagy and socialization (Kingdon 1982, Hillman 1986b, Turkalo & Klaus-Hugi 1999, Klaus-Hugi *et al.* 2000, Elkan 2003; L. Estes pers. comm.). In Congo, Elkan (2003) observed Bongos visit a mineral lick complex from >50 km. They do not usually frequent large expanses of swamp habitat. Bongos generally do not wallow and only cautiously enter deep water. However, during a widespread *Stomoxys* fly outbreak that caused a major die-off in N Congo in 1997, they did wallow in muddy pools along roads and deep water in forest clearings (Elkan *et al.* 2009).

Abundance The Mountain Bongo has been reduced to less than a few hundred individuals (East 1999). Pointing out that the wet season dispersal of Bongos in Aberdares N. P. in Kenya depended on low-level secondary growth on abandoned cultivation sites, Kingdon (1982) thought that the long-term survival of this confined population would be compromised if trees in and around these sites were permitted to reach climax and shade out low-level herbage. The formerly cultivated areas are now dominated by woody shrubs (such as *Toddalia asiatica*) that may be somewhat depauperate in the forbs that Bongos prefer (or may not offer the type of cover that Bongos like) (L. Estes pers. comm.).

The status of the Lowland Bongo in West Africa is uncertain or rare with populations fragmented and declining in many areas (East 1999). In contrast, thousands of Lowland Bongos probably still exist in central Africa. However, they are rare over large areas of closed-canopy forests of N Congo and in the Ituri Forest, DR Congo (Elkan 2003, S. Blake pers. comm., J.A. Hart pers. comm.). The highest recorded density of Bongos occurs in the forest–savanna transition zones in S Sudan (Hillman 1986b). After Sudan, some of the highest concentrations of Lowland Bongos are found discontinuously in Cameroon, Central African Republic and Congo.

Detailed ecological surveys in the Ndoki-Likouala lowland forests of N Congo demonstrated that Bongos occur in highly clumped local distributions, reaching the highest abundance near forest clearings and areas of high herbaceous growth. Although Bongos occur in unlogged primary forest such as Nouabale-Ndoki N. P., they are found in much higher abundance in adjacent logging concessions, which have secondary growth and a high density of forest clearings (Elkan 2003, S. Blake pers. comm.). There are also poorly understood differences in abundance. For example, in both logged and unlogged forests in the Lobeke area of Cameroon there was higher Bongo abundance than for any areas surveyed in N Congo (Elkan 1995, 2003).

Bongo *Tragelaphus eurycerus* male skeleton.

Dense forest habitat, patchy distributions, wide-ranging patterns, retiring behaviour and crepuscular/nocturnal activity patterns hinder estimation of Bongo densities. Hillman (1986b) estimated 1.2/km² in S Sudan based on group-size observations and mineral-lick distribution. Remote camera trapping identified 65 ♂♂ and 109 ♀♀ visiting the Mombongo forest-clearing complex in the Kabo forest concession in N Congo over a six-year period. Using mark-recapture techniques, Elkan (2003) estimated 139 (± 33) Bongos in the Mombongo area during a one-month period in 1996.

East (1999) estimated 28,000 Bongos remaining, with Mountain Bongo populations in the few hundreds, and populations of Lowland Bongo in the order of a few thousands in the west, and tens of thousands in the central African forest zone. However, these estimates must be considered with caution and a large error margin. Patchy distribution, population declines irrespective of habitat availability, rapid ecological change in unstable habitats, and wide ranging behaviour call for extreme caution in extrapolating local abundance estimates to density calculations for large areas (Elkan 2003).

Adaptations With the high point of the body in the lumbar region and head frequently lowered, short legs compared with other tragelaphines (Ralls 1978), and horns that can be laid against its back, a Bongo can run full speed through dense forest. Although they prefer to go under or through objects, rather than over them, they are (like other tragelaphines) capable jumpers. Horns of both sexes, but particularly in the ♀, assist in defending young against predators (Kingdon 1982), and are sometimes employed to break high branches. They are also able to rear up on their hindlegs to reach leaves and twigs at heights of 2.5 m above ground. Although they lack or have very rudimentary external glands, Bongos secrete strong scents from their skin. This odour is hypothesized to assist in locating other individuals despite the dense habitat in which they live. The Bongo's white stripes and its reddish-maroon colouring blend in to the forest's filtered light making detection difficult. Kingdon (1982) noted that although a full frontal view of a Bongo can be quite conspicuous, animals often offset this by turning their striped cryptic backs on a disturbance. By keeping very still in the

Bongo *Tragelaphus eurycerus* myology.

face of any potential threat, Bongos tend to leave the option of flight to the last moment.

Bongos are most active in the evening, night and early morning when, between bouts of feeding and using mineral licks, they often walk long distances at several kilometres/hour. There is one camera-trap record of an old ♀ (and occasionally her calf) spending several hours at a salt-lick in broad daylight (L. Estes pers. comm.). Bongos typically ruminate and rest in the hotter parts of the day (Hillman 1986b, Elkan 2003); *Gilbertiodendron* forest habitat with relatively open understorey as well as dense vine areas were frequently used for resting in N Congo (Elkan 2003) while bamboo habitat provides refuge to Mountain Bongos (Kingdon 1982).

Foraging and Food Diet varies greatly (107 species of food plants recorded in Sudan, 100 in Central African Republic, >80 in N Congo), but consists primarily of browsing on dicotyledonous plants, with some seasonal grazing on grasses (Hillman & Gwynne 1987, Klaus-Hugi *et al.* 1999, Elkan 2003; and see Gagnon & Chew 2000). These observations are borne out also by studies involving carbon isotope analyses (at least, on Mountain Bongos) (Cerling *et al.* 2003). Bongos prefer young leaves and new growth in recently burned or perturbed areas (i.e. post-timber exploitation, tree falls).

In central Africa, just after early rains, Bongos concentrated feeding on seasonally palatable grasses, the new leaves of the highly aromatic invasive herb *Chromolaena odorata*, and *Ipomoea involucreta*, *Macaranga barteri*, *Triumfetta cordifolia*, *Sida alba*, *Paspalum conjugatum*, *Alchornea cordifolia*, *Adenia cissampeloides*, *Cissus dinklagei*, *Manniophyton fulvum*, *Diodia* sp., *Costus* sp. found along roadsides and forest openings (Klaus-Hugi *et al.* 1999, Elkan 2003). During the dry season, they moved further into forest as forage quality and water decreased in ecotone areas. Important food plants included *Thomandersia laurifolia*, *Palisota ambigua*, *Whitfieldia elongata*, *Rinorea* sp. and *Barteria* sp. in closed-canopy forest. *Gilbertiodendron dewevrei* was also occasionally an important food source during rare, intermittent masting periods when Bongos would feed for days on this super-abundant food source (Elkan 2003). Bongos submerged their heads for tens of seconds to feed on algae (*Spirogyra* sp.) at a pond in N Congo. They also seasonally entered cleared fields near villages for manioc leaves and shoots of corn (Elkan 2003).

Mountain Bongos inhabit a very different and botanically less diverse habitat with fewer food plants available. Edmond-Blanc (1960)

identified *Parochetus communis* and *Senecio bigrae* as important food items on Mount Kenya. *Impatiens* spp., *Sericostachys scandens*, *Rubus*, *Asplenium* and *Mimulopsis* spp. are common in the diet at high altitudes in the Aberdares with *Cassia didymobotrya*, *Vernonia auriculifera* and *Crotalaria agatiflora* readily consumed at lower altitudes (Kingdon 1982, L. Estes pers. comm.). Other species commonly encountered as browse/graze plants include: *Cynodon dactylon*, *Pennisetum clandestinum*, *Hypoestes forskalei*, *Plectranthus* spp., *Achyranthes aspera*, *Cyathula* spp., *Vernonia amygdalina*, *Impatiens fischeri* and *I. hoehnelii* (L. Estes pers. comm.).

Bongos visit mineral licks where they consume water and soil high in sodium, other mineral salts and trace elements (Hillman 1986b, Elkan 1995, 2003, Klaus-Hugi *et al.* 1999). Their drive for salt was demonstrated by a concentration of activity around artificial salt-licks in Congo (Elkan 2003). Ingestion of soil with high clay content is thought to buffer the rumen and assist in the digestion of high levels of secondary compounds and alkaloids found in much of its browse (Klaus-Hugi *et al.* 1999, Elkan 2003). When licks become baked, hardpan activity decreased.

Social and Reproductive Behaviour The Bongo is a highly social antelope, and, next to the Common Eland *Tragelaphus oryx*, forms the largest herds of any tragelaphine (Estes 1991a). Aggregations of up to 50 animals have been recorded in the forest mosaic of S Sudan (mean = 9.1, $n = 42$) (Hillman 1986b), although, in dense lowland Ituri Forest, group size is often only a few individuals (range 2–8) (Hart 2001). Mean group size in N Congo was 5.7 (range 2–23; $n = 93$) (Elkan 2003) and in SW Central African Republic, 13 (range 2–28; $n = 78$) (Turkalo & Klaus-Hugi 1999). In the Aberdares, group size ranges from 2 to 21 (Kingdon 1982).

Females and young of both sexes including calves accompanied by an adult ♂ were the most common and largest social grouping in N Congo (Elkan 2003). In contrast to ♀♀, adult ♂♂ are often solitary; 75% ($n = 114$) of solitary individuals observed in N Congo (Elkan 2003) and 78% ($n = 41$) in S Central African Republic (Turkalo & Klaus-Hugi 1999) were ♂♂. However, seasonally, adult ♂♂ form temporary associations with female groups. When not associating with ♀♀, single ♂♂ overlap in home-range, and show little or no territoriality. More than 34 adult ♂♂ visited the Mombongo forest-clearing complex over a six-month period in 1996 in N Congo. These activity levels coincided with high levels of female group visitation of the area.

Resighting of individuals in N Congo has shown that Bongos range over distances >50 km and with broad herd movements that suggest seasonal habitat shifts (Elkan 2003). Home-range sizes on Mt Kenya and the Aberdares show a distinct dry/wet season shift with, tentatively, an annual home-range of 100–300 km² (Kingdon 1982).

Fighting is rare and probably dangerous (Estes 1991a). Aggressive male–male interaction has been observed; however, ♂♂ were not aggressive or threatening towards ♀♀ during courtship (Ralls *et al.* 1985). Mutual tolerance in groups, lack of aggressive behaviour, and larger body size in dominant ♂♂ indicate establishment of dominance hierarchies (Elkan 2003). No fighting was observed in N Congo and other agonistic behaviour was rare; however, ♂♂ did displace other ♂♂ for access to licks and young ♂♂ were observed locking horns and strength testing. Bongos exhibit dominance through lateral presentation with head up and a slow stiff-legged walk (Hamaan 1979, Estes 1991a).

Bongo *Tragelaphus eurycerus* frontal view of signal patterns.

Bongos have a keen sense of smell. Males have been observed wandering through clearings following the scent of a group that had passed hours earlier. They also have been observed to horn ground and rub in soil leaving a strong odour (Elkan 2003). There is some evidence that their body secretions are soluble in water and run off the body in raindrops (Kingdon 1982). This would assist the scent-marking of trails and resting places. Adult ♂♂ frequently mark small trees by rubbing their horns to scrape the bark or breaking them over at 1.25–1.5 m. Although marking of presence seems to be common, no evidence of defence of territories has been observed (Elkan 2003).

Males in the wild followed potentially receptive ♀♀ with a low body posture, neck outstretched and lips curled back exposing the upper gums to test for oestrus (flehmen) (Elkan 2003). Males did not herd ♀♀ but tended to follow behind the group when entering and leaving forest clearings. Ralls *et al.* (1985) categorized Bongo male behaviour towards oestrous ♀♀ in captivity as similar to other tragelaphines and most like that of the Sitatunga *Tragelaphus spekii*. Males regularly test ♀♀ by sniffing and licking the vulva and prodding to provoke urination (Ralls *et al.* 1985). Flehmen behaviour followed sniffing urine, faeces, or a place on the ground where a ♀ had recently lain. Males assumed a 'low stretch' posture laying their head against the female's side often with a soft vocal 'clicking' sound. Mounts were preceded by ♂♂ assuming 'frozen' or 'facing away' posture, a behaviour that may be distinctive to this species (Ralls *et al.* 1985). This type of behaviour was also observed in an attempted copulation observed in the wild in N Congo. Oestrous ♀♀ are more restless and urinate and defecate more often than non-oestrous ♀♀ (Ralls *et al.* 1985). Oestrous ♀♀ engaged in mutual licking with ♂♂. Copulation was preceded by circling away and then back to the ♂ with the ♀ then often sniffing or licking the male's genitals. Females assumed a 'mating face', head and neck extended in a concave curve, raised nose, and mouth open.

Females with new calves lie out for a period prior to joining groups (Kingdon 1982, Elkan 2003). Calves stay close to the mother during the early months and then form close associations with other young Bongos. Bongos are relatively quiet animals and make few vocalizations. Males utter a loud bellow when alarmed or when entering a social group.

Bongo *Tragelaphus eurycerus* adult female.

Reproduction and Population Structure Females are thought to begin breeding at 2.5 years old and ♂♂ probably at 3–4 years (Ralls 1978). There appear to be bi-annual calving peaks in both Lowland and Mountain Bongos. Peaks in Lowland Bongo birthing occur from May to Jun and Sep to Nov in the short and long wet seasons, respectively (Turkalo & Klaus-Hugi 1999, Elkan 2003). As the calves are dropping in May and Sep at the beginning of the wet seasons, forage quality would be high (P. Elkan pers. obs.). Mountain Bongos calve in Jan and Sep (Kingdon 1982).

Gestation periods of 282–287 days (Ralls *et al.* 1985) have been observed in captive Bongos. Oestrous cycle is 21–22 days and oestrus lasts three days (Ralls *et al.* 1985). Captive ♀♀ conceived at 2.3 and 2.7 years of age and inter-birth intervals were 466 and 525 days.

A single calf weighing an average of 20 kg is born (Forthman *et al.* 1993), although twins have been recorded in captivity (Schürer 1999, Ibler 2001). Females with new calves lie out for a period prior to joining groups (Kingdon 1982, Elkan 2003). Calves stay close to the mother during the early months and then form close associations with other young Bongos. In captivity, calves were able to eat vegetation during the first week (Forthman *et al.* 1993). Horns are visible after 2–3 months, growing rapidly to 100 mm after six months and 200 mm by about one year. Observations of young in captivity suggest that Bongo calves exhibit less aggressive behaviour and slower horn development than do Common Elands.

The sex ratio estimates from individually recognized Bongos was 0.6 adult ♂♂ to 1 ♀ (Elkan 2003). Mortality and birth rates for Bongos are not known and are likely to be site-specific. Differences in adult to calf/juvenile and adult to subadult ratio suggest higher mortality in young, probably due in part to Leopard *Panthera pardus* predation (Turkalo & Klaus-Hugi 1999, Elkan 2003). Adult ♂♂ had the highest mortality rate of any age/sex class during a 1997 die-off of Bongos in N Congo (Elkan *et al.* 2009). They live to 25 years in captivity, but are unlikely to attain that age in the wild.

Predators, Parasites and Diseases Young Mountain Bongos are vulnerable to African Rock Pythons *Python sebae*, Leopards and Spotted Hyenas *Crocuta crocuta* during the lying up period (Verschuren 1975), as well as to predation from Lions *Panthera leo*

(D. Western pers. comm.). In Central Africa, all ages, but especially young, are subject to predation by Leopards (Elkan 2003).

Percival (1928) reported that rinderpest drastically reduced the populations of the Mountain Bongo in 1890 and 1896 and populations are thought to have suffered greatly in later epidemics in the early 1900s. Unusual cases of widespread mortality have been registered in both Lowland and Mountain Bongos. A case involving the mortality of a large number of Bongos was reported from the Mau Forest, Kenya in 1960 (Simon 1962). Local hunters indicated that foraging on poisonous second-year growth of an irregular *Mimulopsis* sp. cycle (after the extensive flowering and die-off of bamboo *Arundinaria alpina*) caused extensive mortality not only in Bongos, but also in Forest Hogs *Hylochoerus meinertzhageni* and domestic cattle. Although symptoms of death did not resemble those of rinderpest, Davies (1993b) later argued that this artiodactyl disease was a more likely explanation for the deaths. Resolution of this controversy is of practical importance for the conservation of this species in Kenya. *Theileria* may also be an important disease affecting wild Kenyan populations (P. Reillo pers. comm.).

Parasitological investigation of several Bongos in Congo found evidence of *Elaeophora sagitta* and nematode parasites (Huchzermeyer *et al.* 2001). In Apr and May 1997 a *Stomoxys* fly outbreak contributed to the mortality of large numbers of Bongos and other ungulates over a broad area of the tri-national region of Cameroon–Congo–Central African Republic. A prolonged severe dry season followed by exceptionally heavy rains created ideal conditions for several highly abundant generations of *Stomoxys* flies. Clouds of biting flies attacked large mammals in the region leading to mortality of Bongos, Sitatungas and Yellow-backed Duiker *Cephalophus silvicultor*. Mortality rates were highest in adult male Bongos. Elkan *et al.* (2009) hypothesized that the multifactorial mortality resulted largely from disruption of foraging patterns and the extreme fatigue of attempting to fight off and escape the biting flies.

Conservation IUCN Category: Near Threatened (*T. e. isaaci* – Critically Endangered C2a(i); *T. e. eurycerus* – Near Threatened). CITES: Appendix III (Ghana).

Mountain Bongos are now rare on Mt Kenya and have been substantially reduced in Aberdares N. P. and its surrounding forest reserves. There is evidence of a remnant population in the Mau and Eburu forests, which are both subject to high levels of illegal logging and hunting. The Eburu population, located as it is in a small, isolated forest, is under especially intense pressure (L. Estes pers. comm.). The decline of Mountain Bongo populations in the Aberdares in recent years has been attributed to increased hunting by local people and habitat loss and transformation (Hillman 1986b, T. Butynski pers. comm.), and even to the increased numbers of Lions in the area (D. Western pers. comm.). Although these factors have surely played a role in the decline of Mountain Bongo, the impact of disease has probably been underestimated (L. Estes pers. comm.). The continued grazing of cattle in the forest reserves of Mt Kenya and the Aberdares may have greater implications for Bongo conservation than hunting pressure in terms of disease transmission; cattle have been found all the way up in *Hagenia* forest on the Aberdares plateau in the dry season – in an area where they certainly overlap with Bongos (L. Estes pers. comm.). The negative impact of forest succession as a result of total protection needs further investigation (Kingdon 1982)

and ongoing research at the time of going to press might shed some light on this issue (L. Estes pers. comm.).

Two conservation initiatives are currently in progress on Mountain Bongos, including: (1) a multi-phased international programme to reintroduce captive Bongos from North America to Mt Kenya; and (2) the Bongo Surveillance Programme (BSP), which protects and investigates the status of the remaining wild Bongos in Kenya. The first phase of the Bongo reintroduction programme, spearheaded by the Rare Species Conservatory Foundation (RSCF), began in 2004, when 18 animals were flown from North American zoos to a captive-breeding facility at Mt Kenya Game Ranch, on the north-western slopes of the mountain. The second phase began in 2005, with the commencement of a research programme into the Mountain Bongo's ecology. The research project, currently ongoing, is investigating the configuration of Bongo habitat on both the Aberdares and Mt Kenya, using recently collected field and remotely sensed data. Since 2004, the BSP has been surveying potential Bongo habitat, focusing primarily on the Aberdares, but also Mt Kenya and the Mau and Eburu forests; plans to survey the Cherangani Hills are also afoot. The BSP was created, and is run entirely, by Kenyans local to the Aberdares and Mt Kenya, and is largely responsible for the current state of knowledge about the remaining populations (L. Estes pers. comm.).

Direct threats to Lowland Bongo conservation include snare hunting associated with expanding commercial forestry exploitation, high demand for Bongo trophies, and changing land use (Elkan 1995, 2003). Traditionally, due to taboos against eating of the meat, Bongos

Bongo *Tragelaphus eurycerus*.

are not considered a preferred game species by local people in many parts of Africa, such as N Congo, S Sudan, SW Central African Republic and SE Cameroon (Hillman 1986b, Elkan 1995, 2003). However, there is still heavy loss due to snaring that indiscriminately kills young and wounds adults. Eroding traditional beliefs and expanding commercial hunting are creating new pressures on populations and its meat is sometimes smoked and sold as 'buffalo'. Bongos are also the primary target of tourist safari hunting in the forests of central Africa. Demand for Bongo hunting safaris has been increasing greatly over the past decade and the use of dogs and inadequate regulation has resulted in over-hunting in several areas (Elkan 1995, 2003). H. Planton and A. DeGeorges (pers. comm.) reported that hunter success and trophy quality were declining in Cameroon. Hunters have argued that 'trophy' ♂♂ taken are 'solitaires' and are too old and no longer involved in mating. While this may sometimes be the case, age estimation data indicate that many of these ♂♂ observed as solitary are likely to be reproductively active (P. Elkan pers. obs.).

Although the distribution and numbers of Lowland Bongos have declined over large parts of their former range, and particularly in West Africa, they remain patchily distributed, with localized concentrations in areas of favourable habitat (East 1999). Populations of Lowland Bongos in Central Africa receive protection in Dzanga-Ndoki N. P. and Bangassou areas of Central African Republic, Lobeke N. P. (Cameroon) and in Nouabale-Ndoki and Odzala National Parks (Congo) (East 1999). In Gabon, they are reliably recorded from Mwagne, Minkebe and Ivindo National Parks (Maisels *et al.* 2004, P. Henschel pers. comm.). In Congo, the highest known Bongo densities occur in the Kabo and Pokola logging concessions (Elkan 2003). In West Africa, where declines have been more severe, the Lowland Bongo remains common in only a few areas, such as Taï N. P. (Côte d'Ivoire), Sapo N. P. (Liberia) and Kakum N. P. (Ghana) (East 1999). East (1999) estimated that perhaps 60% of Bongo numbers were confined to protected areas.

Because the highest known abundances of Bongos in central Africa occur in logging concessions not protected areas, an approach is needed that incorporates both protected areas and logging concessions. The goal is to devise a strategy that reduces indiscriminate killing of Bongos by snares, strictly regulates and monitors safari hunting outside of reserves, and incorporates a landscape analysis of the effects of different land ownership, land use practices and resource needs of local people. This approach is being pioneered in Congo by establishment of community-supported subsistence hunting regulations in logging concessions that aim to ensure a sustainable supply of wildlife meat without illegal killing of Bongos and other protected species. Forest blocks are zoned as non-hunting or subsistence hunting areas. Separate hunting zones are designated for each village and logging camp. Transport and

commercial sale of meat across these zone boundaries is prohibited and regulations are enforced by a staff of both government officers and ecoguards (Elkan 2003). Rational allocation of hunting rights, promotion of alternative meat sources for logging company employees, and wildlife law enforcement are developed and combined with an intensive education programme that emphasizes both general conservation and the utilitarian practicality of non-hunting areas adjacent to hunting zones.

Current Bongo distribution patterns are patchy and not well understood. It is important to begin developing and testing an ecological model of their distribution and conservation based on data on abundance and distribution in relation to forest cover and condition, critical forest clearing habitat and current and historical logging and hunting. The model can then be used to explore how the Bongo will respond to different logging and other anthropogenic factors.

Measurements

Tragelaphus eurycerus

T. e. eurycerus

HB (♂♂): 2043 (1860–2190) mm, n = 12

HB (♀): 2010 mm, n = 1

T (♂♂): 561 (530–610) mm, n = 13

Sh. ht (♂♂): 1210 (1100–1260) mm, n = 13

Sh. ht (♀): 1220 mm, n = 1

Congo (P. Elkan pers. obs.)

Record horn length is 89.2 cm for a pair of horns from the Kerre R., Central African Republic (Rowland Ward)

T. e. isaaci

HB: 1700–2500 mm

T: 450–650 mm

Sh. ht: 1100–1250 mm

WT (♂♂): 362 (335–400) kg, n = 3

WT (♀♀): 229 (182–276) kg, n = 7

Kenya

Body measurements: Haltenorth 1963 (mean and sample number not given)

Weight: L. F. Bosely (pers. comm.)

Record horn length is 87.9 cm for a pair of horns from Mt Kenya, Kenya (Rowland Ward)

Tragelaphus derbianus GIANT ELAND (LORD DERBY'S ELAND)

Fr. Éland de Derby; Ger. Reisenelenantilope

Tragelaphus derbianus (Gray, 1847). Ann. Mag. Nat. Hist. (1) 20: 286. Gambia, Western Africa.LEFT: Giant Eland *Tragelaphus derbianus* male.ABOVE: Foreleg/metacarpus proportions compared in Greater Kudu *T. strepsiceros* (left), Giant Eland *T. derbianus* (centre) and Common Eland *T. oryx* (right).

Taxonomy First described by Dr J. E. Gray, keeper of the Department of Zoology at the British Museum in London from 1840 to 1874, from horns, then skins, sent from Senegambia (type specimen). The species was originally placed in the genus *Boselaphus*, then *Oreas*, and then *Antilope*. *Taurotragus*, referring to the size and shape of the largest antelope, rather massive and more or less ox-like, has been used since the late 1800s, but is here included in *Tragelaphus* (see genus profile). The species has been treated as conspecific with the Common Eland *Tragelaphus oryx* (Haltenorth 1963), but is considered a distinct species by most authorities.

Four Giant Eland 'races' have been recognized in the past (Clark 1931): *T. derbianus derbianus* from Senegambia; *T. d. cameroonensis* from Cameroon; *T. d. congolanus* from Congo; and *T. d. gigas*, from Sudan. Only two subspecies are now recognized: *T. d. derbianus* is dedicated to the 13th Earl of Derby who employed the collector of the first horns sent to England, while *T. d. gigas* was described by von Heuglin from a pair of horns collected during travels to the White Nile region in 1863 (von Heuglin 1864). Synonyms: *cameroonensis*, *colini*, *congolanus*, *derbii*, *gigas*, *typicus*. Chromosome number: $2n = 31$ in ♂ (translocated Y) and 32 in ♀, the same as the Common Eland *T. oryx* (Nguyen *et al.* 2008).

Description The largest of all antelopes, massive, and often said to show a 'bovine' appearance (though more finely shaped) and sometimes exceeding the size of the African Buffalo *Syncerus caffer*. Long muzzle, but much narrower than that of an ox, with a black mark starting below the eyes and extending down to the nostrils (narrow on ♀ and young, wide on old bulls); there is a white chevron between/below the eyes, except on old dark bulls. Ears broad and expanded, rufous outside, whitish with black patches on the hind margins. There is a mat of dark hair on the forehead of adult ♂♂; a prominent dewlap commences below the chin. Coat hair short,

general colour ruddy fawn, sides (shoulder to rump) of body marked with usually 10–18 long vertical white stripes. A mostly black stripe runs along neck and back, with white hair on top of stripes. There is a short, darkish mane on the bull's neck and withers; neck covered with rufous grey to blackish hairs, bordered at its rear end by a paler (♂♂) or even white (♀♀) collar. Dark marks are present behind the knees of the forelegs, and surrounding all four pasterns and fetlocks, with white spots often marking the front face of pasterns. Internal side of legs paler than body, or whitish. Hooves grey. Tail long, reaching hocks, with terminal black tuft 100–150 mm below the hocks, always moving (the most prominent detail when seen from a distance in dense bush). Females more lightly built and smaller, with no mat of hair on the forehead. Variation in size and shape of dark and white marks as well as horns permit individual identification. Females have two pairs inguinal nipples.

Horns, present in both sexes, are thick-set, very large and massive, especially in ♂♂ (smaller in ♀♀), diverging from the base and almost straight, tightly spiralled, with anterior ridge more pronounced than the posterior.

Geographic Variation

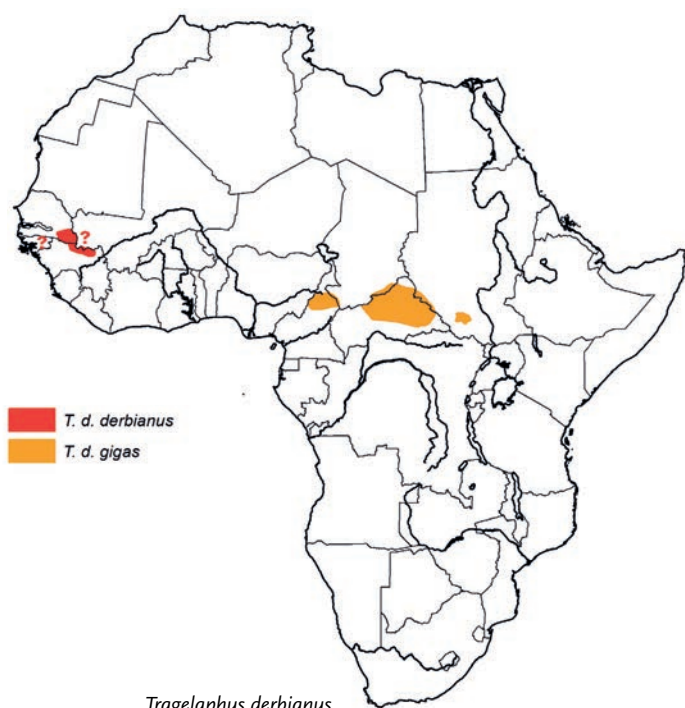

T. d. derbianus (Western Giant Eland): Senegal, Mali, Guinea and possibly E Guinea-Bissau. Bright rufous ground colour.

T. d. gigas (Eastern Giant Eland): Cameroon, Central African Republic, Chad and Sudan. Somewhat larger (the name Giant Eland is most applicable to this form), with a sandy ground colour.

The number of white stripes has often been noted as a distinctive feature between these taxa, with the western subspecies (*derbianus*) said to have more stripes (approximately 15) than the eastern (*gigas*; 12). However, individuals observed in Central Africa may have as many as 10–18 stripes (mean = 14) (H. Planton pers. obs.), and individuals of the western subspecies 12–16 stripes (mean = 14) (M. Antonínová & P. Hejčmanová pers. comm.).

Similar Species

Tragelaphus oryx. Allopatric species from open or lightly wooded savannas of eastern and southern Africa. General appearance

similar, though body slightly smaller, colour fawn or tawny, turning to greyish or bluish-grey with age, except for lower parts of legs; sides almost uniform or lightly striped (4–9 stripes); mane only on back of neck; dewlap commencing on throat; chevron often not visible between eyes; horns shorter, thinner; ears narrower, more pointed, without black marks.

Distribution Endemic to Africa. The historical range of the Giant Eland is not well known, but they probably occurred throughout the relatively narrow belt of savanna woodland extending across West and central Africa from Senegal to the Nile (East 1999).

The distribution of the Western Giant Eland is centred on and around SE Senegal, with the Eastern Giant Eland occurring in the central African region. The Western Giant Eland has been formerly reported from Senegal to Togo (Bigourdan & Prunier 1937, Baudenon 1952, East 1990), though its occurrence in Togo might have been a mistaken confusion with the Bongo *Tragelaphus eurycerus* (Grubb *et al.* 1998). The distribution has been reduced since the 1950s to small, scattered populations (Jeannin 1951). The subspecies still occurs in SE Senegal (Chardonnet 1997, G. Mauvais pers. comm.), the far north of Guinea (Sournia *et al.* 1990, Chardonnet 1997, Darroze 2004), probably SW Mali (Chardonnet 1997, Darroze 2004) and possibly E Guinea-Bissau (Chardonnet & Limoges 1990, East 1999).

The Eastern Giant Eland was formerly distributed from NE Nigeria to NW Uganda; it is now apparently extinct in both of the aforementioned countries, surviving in the former in the northern part of Gashaka-Gumti N. P. until the 1970s (Anadu & Green 1990), and being exterminated in the Uganda part of its range during military operations in 1970 (Kingdon 1982). The species now occurs mainly in NE Central African Republic, and in N Cameroon, with herds crossing the Chad border to the east; occasional vagrants may enter Nigerian territory (East 1999). There has been some recolonization by Giant Elands of hunting blocks of SE Chad since

the late 1990s (P. Chardonnet pers. comm.). They may still occur widely in SW Sudan (and indeed were recently recorded in Southern N. P.; Fay *et al.* 2007), and perhaps still occasionally visit NE DR Congo and NW Uganda (East 1999).

Habitat Giant Elands inhabit woodlands and forested Soudanian to Guinean savannas (1000–1500 mm rainfall in 5–7 months/year), and are never far from hilly/rocky landscapes or from water. They are frequently found in or near *Isoberlinia doka* woodlands (Kingdon 1997), although their range includes *Terminalia–Combretum–Afzelia* woodland, where *Isoberlinia* is not found (Bro-Jørgensen 1997). The western distribution corresponds to *Combretum glutinosum–Annona senegalensis* woodland and a mosaic of grass and woody savanna dominated by Combretaceae (Nežerková *et al.* 2004). Giant Elands move large distances daily (5–20 km/day) and all year round, and usually return to the same places during the same season. Wet season habitat is not clearly known, though it is widely believed that they spend the wettest months on rocky hills.

Abundance Densities in the order of 0.15–0.30/km² have been recorded, with great variations as herds in Cameroon move a lot within home-ranges of some 1000–1500 km² (H. Planton pers. obs.); they can be locally abundant during a few weeks/months and then totally absent for months. Thus, the same herd can be observed in very distant places at different times and densities are easily overestimated. A single study in Central African Republic reports an average home-range of 223 km² (Graziani & d'Alessio 2004).

Although no specific count has been carried out, it is estimated that some 200 or less individuals of the Western Giant Eland survive in Senegal (G. Mauvais pers. comm.). According to East (1999), there are probably more than 15,000 Eastern Giant Elands remaining, with over 12,500 in the Central African Republic. Since the early 1990s, numbers have tended to increase, at least for Cameroon (Planton *et al.* 1995), Chad and the Central African Republic (Blom *et al.* 1995). There is no information on numbers surviving in Sudan, although Fay *et al.* (2007) estimated a population of 165 for Southern N. P.

Adaptations Giant Elands drink daily when water is available, but even youngsters will trot or walk tirelessly all day long if disturbed, without stopping at any water point. They browse day and night, and do not rest except, when undisturbed, during the heat of the day. They use their strong horns to knock down or break branches and gain access to leaves of trees. Giant Elands have an excellent sense of smell and hearing, as well as excellent sight even at long distances.

The visual impact of the black-and-white markings on legs and ears is greater than in the Common Eland. This difference could be related to their less open habitat, to a greater role for ear and foot signals or to carry-overs from an ancestral condition. Ears are substantially larger than in the Common Eland and this, too, could be due to evolutionary inertia, but is more likely to represent selective pressure to maximize acuity of hearing in wooded environments.

Prior to a well-marked breeding season there are colour (and, perhaps, physiological and olfactory) changes that are exclusive to the foreheads and necks of breeding bulls. This overall darkening of the bulls' forequarters might signify a visuo-olfactory advertisement of the males' reproductive condition. A dense brush of hair on the

forehead of adult ♂♂ is often employed in 'marking' behaviour. Supposed territories are marked by adult bulls urinating on a patch of moist soil, and they then rub their forehead and horns to pick up the odour. Bulls anoint themselves on their sides and back and thereby more effectively proclaim their presence. The thick mat of woolly dark hair on the forehead acts as a paintbrush and allows the bull to leave samples of his scent on tree trunks at just the right level to be noticed by other elands (Ruggiero 1990).

Foraging and Food Giant Elands feed mostly on leaves, shoots, herbs and fruits (but occasionally on grasses), and are classified as browsers by Gagnon & Chew (2000) in their review of the dietary preferences of African bovids. Movements are to a certain extent determined by the presence of certain trees or shrubs, the young leaves of which form their favourite diet. Feeding habits have been observed in several places, but systematically studied only in N Cameroon (Bro-Jørgensen 1997, Michaux 1998), where more than 80 plant species were eaten (the ingestion of 16 of these having been directly observed). Shortly after bushfires, a lot of dried leaves and dry fruits, and ashes, are eaten. During the driest season (Jan–Mar), they feed mainly on *Terminalia* spp. and *Combretum* spp. leaves, which remain important until the rains (Jun). Where *Adenodolichos* sp. occurs, herds will actively look for sweet young shoots of this plant after fires and until the rains. *Isobertlinia* spp. leaves are eaten during the dry season, but never exceed 20% of the diet. When rains fall, Giant Elands start looking for *Tephrosia* spp. and *Acacia* spp. leaves and pods. Legumes form by far the major part of their diet during the wet season (40–85%). Grasses can be eaten all year round, but never exceed 4–5% of the diet. Salt-licks are visited every day when possible.

Social and Reproductive Behaviour Herds comprise ♀♀ and young of both sexes, plus young adult ♂♂ and sometimes adult breeding bulls. The latter regularly wander alone or in small male groups outside breeding herds. Herd size varies a lot according to season. Most often herds include about 20–30 individuals; large herds of 150 individuals and more are observed early in the dry season (Dec and Jan: Cameroon), before the mating season, and stay together almost until the rains (Jun). In such herds, an adult ♀ often calls continuously, which has the effect of keeping youngsters together near her (H. Planton pers. obs.). Before and during the wet season, herds tend to split into smaller groups of less than ten, often a few ♀♀ and one ♂ plus young. The same herd can be observed in various places of the home-range over which elands move continuously. They are locally abundant for a few weeks/month and then move to another part of the range.

Relations between individuals within the group consist mainly of smelling or licking or rubbing nose, mouth, forehead, horns, ears, belly, tail and anogenital region (Altmann & Scheel 1976). Close relationship is sometimes observed between two specific individuals for a couple of days, during which they often rest their heads on each other's back. Males, mainly young, seem to establish their status in the group's hierarchy by simulating threats and fights, often kneeling, near muddy places or salt-licks. The dominant action is to charge the other, head down, and/or snort noisily; the weaker usually gives up and walks away. However, serious fights are sometimes observed or evidenced by scars or broken horns. These often occur early in the wet season, but also during the mating season. Fighting ♂♂ engage

Giant Eland *Tragelaphus derbianus* head in profile.

their horns and wrench their heads sideways in an effort to twist each other's neck and unbalance their opponent. Marking behaviour by adult ♂♂ has been mentioned earlier.

Before mating, the bull approaches the ♀ with neck and head stretched out. The ♀ jumps aside then pushes the ♂ away. The ♂ tirelessly tries again to approach, turns around her, smells her, rests his head on her rump, until she is ready to mate. Pregnant ♀♀ tend to stay together with young individuals, while breeding bulls wander in search of other ♀♀ on heat. Young often stay together and playfully chase each other among and around the adults (Ruggiero 1990). Females accompany their offspring for about one year.

Giant Elands have often been said to be silent. Actually, when undisturbed and browsing, they often sniff and growl discreetly; the ♀ keeps contact with her youngster by a high-pitched call, to which the latter answers. Though they can often be close to other species, Giant Elands very seldom mix with them. Like Common Elands, they are easily tamed when captured as young, and can behave then like domestic stock.

Reproduction and Population Structure In Cameroon, mating mainly takes place in the first half of the dry season (Dec–Feb). Prior to this, changes in the breeding bull's forehead and neck have been mentioned and are quite noticeable in the field (H. Planton & I. Michaux pers. obs.). Mean gestation length is 39 weeks. Calving has yet to be observed in the wild, but occurs between Sep and Jan, i.e. before (peak) and shortly after the last rains. Under captive conditions in Senegal, calving takes place between Nov and Feb, in the early dry season (Al-Ogoumrabe 2002, M. Antonínová & P. Hejčmanová, pers. comm.). Usually a ♀ gives birth to a single calf, about 25–35 kg, which stays hidden and out of the herd for one week. The calf starts browsing from one week old, and is weaned after six months. Maturity is reached between 15 and 24 months, and animals are full size by 4–5 years. Bulls do not usually succeed in mating before they are seven

Giant Eland *Tragelaphus derbianus* subadult male.

years old. Sex ratio among calves is 1 : 1, but adult ♀♀ outnumber adult ♂♂ (Altmann & Scheel 1976, H. Planton pers. obs.).

Predators, Parasites and Diseases Little information is available regarding predators, which include Lions *Panthera leo* and African Wild Dogs *Lycaon pictus*, while Leopards *Panthera pardus*, Spotted Hyenas *Crocuta crocuta* and Cheetahs *Acinonyx jubatus* also prey on calves, which ♀♀ try to protect.

Major epizootic diseases cause great variations in numbers. In particular, Giant Elands have suffered heavy mortality from rinderpest, e.g. in the early 1900s (Blancou 1960), to which it is said to be more susceptible than any other antelope. Its demise in Gambia has been attributed primarily to the devastating effects of this disease (Camara 1990). Populations in the central African region crashed by 60–80% during and after the 1983–84 rinderpest outbreak, but have almost recovered now facilitated by the bush encroachment that accompanied the severe reduction in elephant numbers by poachers during the 1980s and the prevalence of uncontrolled fires (East 1999).

Studies on parasites have been carried out in Cameroon through helminthological necropsies and year-round faeces collection/analysis

(Michaux 1998). Cestodes, trematodes and nematodes have been found, but in low numbers compared with neighbouring wild grazers (e.g. Kobs *Kobus kob*) and in very low numbers and species diversity compared with domestic stock. Parasitic load was almost nil in the dry season. The Giant Eland is a new host for five parasite species (*Moniezia monardi*, *Haemonchus vegliai*, *Cooperia yoshidai*, *Cooperia* sp. and *Ostertagia angusdunni*), and two other species found might represent undescribed new species of *Cooperia* (Michaux 1998).

Conservation IUCN Category: Least Concern (*T. d. derbianus* – Critically Endangered C2a(ii); *T. d. gigas* – Least Concern). CITES: Not listed.

Uncontrolled hunting (notably assisted by fire) and loss of habitat have contributed greatly to the reduction of Giant Eland numbers, particularly in West Africa where they have been exterminated throughout most of their former range. Traditionally, the Fulani people did not hunt them, as they are believed to transmit diseases and cast spells. Their current distribution range includes a number of sizeable protected areas, including Niokolo-Koba N. P. and Falémé Hunting Zone in Senegal (*derbianus*); Faro, Bénoué and Bouba Ndjida

National Parks and most of the 27 surrounding hunting concessions in N Cameroon, Bamingui–Bangoran and Manovo–Gounda–St Floris National Parks and most of the hunting blocks in N and NE Central African Republic, and Southern N. P. in Sudan (*gigas*). Further development and maintenance of sustainable trophy hunting and improved protection and management of national parks within its range states will be essential to ensure this antelope's long-term survival (East 1999).

Attempts to capture Giant Elands and establish herds of both subspecies outside the species' natural distribution area have been made on at least ten occasions for purely commercial purposes. The Eastern Giant Eland is held in captivity in two countries outside their distribution range: South Africa and the USA. Historical captures were undertaken in Sudan (1938–46), Cameroon (1958) and Chad (1967–70). Of an unknown number of Giant Elands handled, 31 were delivered to six European or American zoos, none of which has any representation in the current captive populations. More wild animals were caught in 1985 in the Central African Republic. The survivors (3 ♂♂, 5 ♀♀) were the initial founders of the current North American captive population (Romo 2001). Animals in captivity derive from the population established in the USA, initially at Cincinnati and Los Angeles zoos, from nine wild-caught animals imported from the Central African Republic in 1986. As of 23 December 2011, the North American population stood at 49 individuals (20 ♂♂, 29 ♀♀) in five institutions: San Francisco Zoological Gardens, White Oak Conservation Center, San Diego Zoo Safari Park, Miami Metrozoo and Houston Zoo. This suggests a 30% decline compared to the number of 69 reported in March 2004 (ISIS records).

In mid-2000, a private South African capture team caught 23 Giant Elands in Central African Republic, of which two died and 21 were flown to Togo. IUCN's Antelope Specialist Group has no information on the fate of the ten captive Giant Elands that are believed to have remained in Togo (East 2001), but 11 of the 21 were later shipped to John Hume's Mauricedale Game Ranch (Mpumalanga, South Africa), with a three-month temporary import permit. Four more died there, and the seven survivors were moved to Johannesburg Zoo in December of the same year following an outbreak of foot-and-mouth disease (East 2001, Estes 2003), shortly after which another one died. The two remaining ♂♂ died during blood transfusion procedures, and since then there have been additional age-related deaths (D. Moss pers. comm.). The survivors, two ♀♀ only, are held at Johannesburg Zoological Gardens. No births have been reported in RSA since October 2001 (ISIS records).

No Western Giant Elands are known to have been held in captivity until recently. Captures made by San Diego Zoo Safari Park in Falémé Hunting Zone, Senegal, in 1979, resulted in all nine animals dying during or shortly after capture (S. Diouf pers. comm.). The next captures were conducted in Niokolo-Koba N. P., Senegal, in 2000

by a South African team for the Ministère de l'Environnement et de la Protection de la Nature and private Société pour la Protection de l'Environnement et de la Faune au Sénégal. Some 126 animals were removed alive from the park, including nine Giant Elands (eight ♀♀ and one ♂). Some of these animals were shipped to South Africa, but none of the elands. Three of the elands died in quarantine, the six survivors (one ♂, five ♀♀) were kept in a 25 ha enclosure (enlarged to 50 ha in 2004) of unsuitable habitat in Bandia G. R., Senegal, just next to exotic (South African) species including Common Elands, with which they could potentially have hybridized (East 2000). There were four births at Bandia in 2002 (Nežerková *et al.* 2004), and 30 in total between 2000 and 2006 (M. Antonínová & P. Hejčmanová pers. comm.). A second enclosure was built in Fathala Reserve, to which a male-only group (9) and a breeding nucleus (1, 3) were translocated in mid-2006 (Antonínová *et al.* 2006). In 2009, the semi-captive population comprised 54 individuals (26 ♂♂, 28 ♀♀), with an annual population growth of 1.4% (Koláčková *et al.* 2011).

Further translocation of Giant Elands to areas such as private hunting reserves outside the species' natural range could potentially have serious consequences in terms of spreading diseases and destroying trophy hunting activities in West and central Africa, which are currently the main support and reason for wildlife conservation in these regions.

Measurements

Tragelaphus derbianus

T. d. gigas

HB: 2620–2930 mm, n = 30

T: 600–700 mm, n = 30

HF c.u.: 100–110 mm, n = 30

E: 230–280 mm, n = 30

Sh. ht: 1650–1780 mm, n = 30

N Cameroon (H. Planton & I. Michaux pers. obs.)

Depierre & Vivien (1992) recorded a maximum HB of 3200 mm

Average estimated weight is around 450 kg for ♀♀ and 900 kg for ♂♂ (H. Planton pers. obs.); Haltenorth & Diller (1980) recorded a mass of 300 kg for ♀♀ and 1000 kg for ♂♂

Record horn length for *T. d. gigas* is 142.9 cm for a pair of horns from Ouanjia R., Central African Republic, and for *T. d. derbianus* the record is 115.6 cm for a pair of horns picked up from an undefined locality (Rowland Ward)

Hubert P. Planton & Isabelle G. Michaux

Tragelaphus oryx COMMON ELAND

Fr. Éland de cap; Ger. Elanantilope

Tragelaphus oryx (Pallas, 1766). Misc. Zool. p. 9. Known to the Dutch 'ad Promontorium B. Spei', restricted to South Africa, Western Cape Prov., near Cape Town by Shortridge (1934: 607).

Common Eland *Tragelaphus oryx* male.Common Eland *Tragelaphus oryx* female.

Taxonomy The Common Eland *Tragelaphus oryx* and Giant Eland *Tragelaphus derbianus* have been considered conspecific by some authors (e.g. Haltenorth 1963), but are usually treated as full species. Three subspecies are generally recognized (Ansell 1972, Kingdon 1997), although their validity requires confirmation. Lorenzen *et al.* (2010) recorded a significant regional divide between mtDNA lineages in Common Eland in East and southern Africa, and posited a more recent origin of the East African population that could result from colonization following extinction from the region. Synonyms: *alces*, *barbatus*, *billingae*, *canna*, *kaufmanni*, *livingstonei*, *livingstonii*, *niediecki*, *oreas*, *pattersonianus*, *selousi*, *triangularis*, *typicus*. Chromosome number: $2n = 31$ in ♂, and $2n = 32$ in ♀, the difference being due to a Y-autosome translocation; the X chromosome is large and acrocentric (Wurster & Benirschke 1968, Wurster 1972, Buckland & Evans 1978, Robinson *et al.* 1997). There are two well-documented records of hybrid male offspring between a Common Eland and Greater Kudu *Tragelaphus strepsiceros*, one known to be sterile, the other unknown (Jorge *et al.* 1976, Van Gelder 1977a).

Description Common Elands are large, cow-like bovines, with straight spiral horns and a dewlap. The pelage is tawny with short hairs, becoming blue-grey with age, especially in ♂♂. There are variable white stripes on the back and flanks, which usually become less distinct with age. The pelage is whitish on the belly, inside the legs and ears and above the hooves. A dark mark is present above the knee on the back of the forelegs. Dark hair on ridge along back and on tufted tail tip. The dewlap is long, thin, pendulous, with a terminal tuft that is lost in older ♂♂. Neck thick and muscular, darker than body; there is no mane, but pale curly hairs on the upper surface. Tufts of hair on the nose and forehead vary in size and colour between individuals and over time within individuals. The mat of hair on the

forehead has a strong smell due to a secretion from a glandular area in the skin (and frequent rubbing in urine). Females are smaller than ♂♂, with the dewlap much smaller and thicker, a terminal tuft of black hair, and no facial hair tufts. Females have two pairs of inguinal nipples.

Horns, present in both sexes, are nearly straight, slightly diverging, with a heavy spiral ridge at the base. Horns of oldest ♂♂ are shorter than those of younger animals. The horns of adult ♀♀ are less heavy and thinner in diameter and more uneven, and without the heavy spiral ridge at the base. Age determination based on horn growth and teeth eruption is discussed by several authors (Kerr & Roth 1970, Attwell & Jeffery 1981, Jeffery & Hanks 1981). Horn buds are present at birth, and the horns grow rapidly until about seven months of age, and thereafter more slowly. At about 18 months of age, the horns of ♂♂ clearly show signs of the developing spiral ridge at the horn base. In the dentition, molars 1, 2 and 3 erupt at 6–8, 14–20 and 24–27 months, respectively, and permanent premolars erupt at 36–37 months; full adult dentition is attained in the fourth year of life.

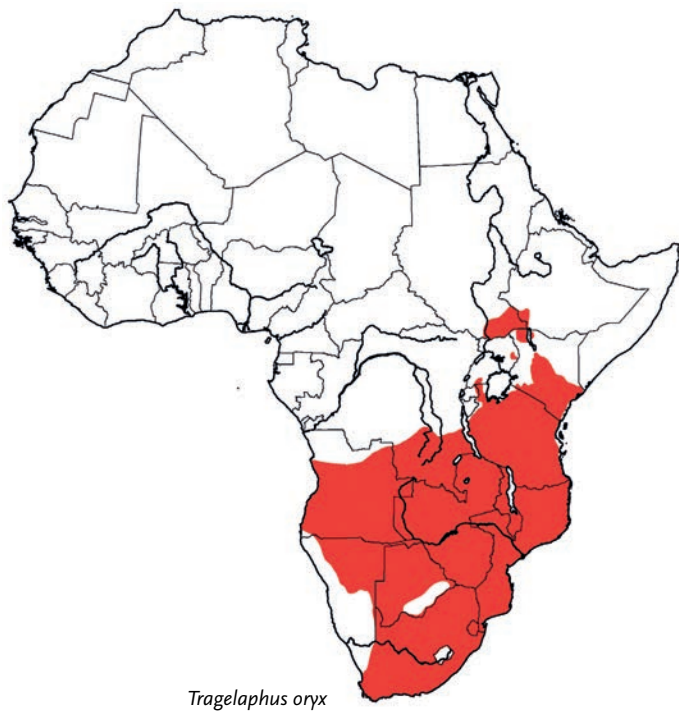

Geographic Variation

T. o. oryx: Southern Africa, with its range extending north to S Botswana and N Namibia.

T. o. livingstonii: East-central African woodland areas.

T. o. pattersonianus: Tanzania northwards.

Common Elands in the southern part of the range (*T. o. oryx*) are dull fawn in colour, the white stripes on the body not particularly distinct, and having a dark brown mark on the back upper region of the forelegs. Common Elands further north have distinct body stripes, but a less distinct dark mark on the back of the forelegs; body colour tends to be richer in Common Elands from northern areas. However, there is a large degree of intergradation and also considerable variation within

*Tragelaphus oryx*

regions. For example, animals in Zimbabwe show traits characteristic of both *T. o. oryx* and *T. o. livingstonii*. Likewise, Common Elands from Angola have been referred to the subspecies *T. o. livingstonii*, although Ansell (1972) noted that Angolan Common Elands occur in an area of intergradation between the nominate form and *livingstonii*. Crawford-Cabral & Veríssimo (2005) note that Angolan animals are more comparable to the nominate form, and thought that at least animals from the west of the country were representative of *T. o. oryx*.

Similar Species

Tragelaphus derbianus. Savanna of West Africa and central Africa in N Cameroon, Central African Republic to SW Sudan (west of the Nile R.). Larger, with longer horns; horns in ♂♂ are longer, more widely splayed, and have a looser spiral; neck of ♂ darker, with dewlap hanging from jaws and neck only, rather than continuing between legs; ears broader, and more conspicuously marked, as are hocks.

Distribution Endemic to Africa, being widespread in savanna and woodland areas in eastern and southern Africa from SE Sudan and SW Ethiopia southwards to South Africa.

Historical Distribution From the Cape Peninsula (South Africa) to forest margins in the Congo Forest basin, the Nile flood-plain and arid N Kenya. Interestingly, a fossil specimen attributed to the Common Eland (and not to the older, now extinct *T. arkelli*) has been found at Ternifine in Algeria (Arambourg 1962).

Current Distribution Still present in much of its former range, except in Burundi, where the species is considered extinct, and Uganda and Rwanda, where it is close to extirpation (East 1999). In Sudan, Common Elands are confined to the south-east, where they still occur in Boma N. P. (Fay *et al.* 2007); in Ethiopia they are known only from the Omo region (Hillman 1988a, East 1999). In Angola, where it was formerly widespread, the species is also believed to be

Lateral, palatal and dorsal views of skull of Common Eland *Tragelaphus oryx*.

close to extinction, although there is no recent information on its status across much of the country. In South Africa, natural surviving populations are confined to the Northern Cape near Botswana (and where populations move into the area from S Botswana), parts of the North West and Limpopo provinces, and in the KwaZulu–Natal Drakensberg mountains (East 1999). In Lesotho, Common Elands occur only in Sehlabathebe N. P. (Lynch 1994). Within the rest of its range, it has been increasingly restricted to protected areas and regions with low human populations. Common Elands have been widely reintroduced in southern Africa (e.g. to Zimbabwe, many parts of South Africa, and Swaziland).

Habitat Common Elands occupy a wide variety of habitats, from semi-desert scrub in the Kalahari, to open *Brachystegia* woodland, to alpine moorlands on the slopes of Mt Kenya, Mt Kilimanjaro, the Nyika Plateau and the KwaZulu–Natal Drakensberg. In the KwaZulu–Natal Drakensberg, they occur up to 2400–2700 m, favouring slopes of 20° or less (Rowe-Rowe 1983, 1994), while in East Africa they have been recorded to 4750–4890 m on Mt Kilimanjaro (Grimshaw *et al.* 1995; and see Kingdon 1982). They are not found in deep forest, in true deserts, or in completely open grassland, though they do occur in grassland with good herb cover or which is interspersed with browsing habitat along drainage lines. Although they no longer occur in coastal regions, they do still occur at relatively low altitudes throughout their range.

Abundance Estimated to number more than 130,000 in the wild (correcting for undercounting biases in aerial surveys), with local density estimates (based on aerial counts) ranging from 0.05 to 0.4/km² (e.g. Laikipia Ranchlands in Kenya, Selous in Tanzania, Etosha N. P. in Namibia and Kgalagadi Transfrontier Park). Higher density estimates (0.6–1.0/km²) have been obtained in areas such as Omo N. P. in Ethiopia and Nyika N. P. in Malawi; ground surveys reveal similar estimates in areas such as Lake Nakuru N. P. (Kenya) and De Hoop N. R. (South Africa) (East 1999). The largest populations are in Namibia (ca. 32,000, where the majority are on private land), Tanzania (ca. 24,000), Zimbabwe (ca. 14,000), Botswana (ca. 14,000) and Kenya (ca. 13,000).

Common Eland *Tragelaphus oryx* adult male myology.

Common Eland *Tragelaphus oryx* skeleton

Adaptations Common Elands are unusual among browsing bovinines since they move long distances in search of ephemeral food sources. They have other attributes that are more typical of grazers such as an open social system. This life-style allows Common Elands to exploit a resource that is not available to other browsers – bushy vegetation and herbs sparsely scattered in grassland. In the Kalahari, the only other large browsers (Greater Kudu) are confined to patches of thicker vegetation, while Common Elands move freely through the system, and make use of dune areas, where the only bushy vegetation consists of dwarf shrubs.

Adaptations to a mobile life include the ability to go without water for prolonged periods. While they will drink when water is available, they are also able to obtain sufficient moisture from their food. Common Elands followed on a daily basis using satellite technology in the south-western Kalahari in Botswana never went close to a water source throughout the entire dry season (C. Thouless pers. obs.). Common Elands have a number of physiological adaptations that allow them to survive without drinking. Their body temperature can vary substantially. Under experimental conditions, body temperature increased from 33.9 to 41.2 °C while ambient temperature was kept at 40 °C, although body temperature generally remained below ambient temperature once it had exceeded 40 °C. The excess heat accumulated during the day is dissipated at night through conduction and radiation, and in order to reduce water loss at night Common Elands breathe more slowly and deeply (Taylor 1969). Recent studies have shown that selective brain cooling does not occur in Common Elands, and brain temperature remains constant at around 0.4 °C above carotid blood temperature (Fuller *et al.* 1999). Common Elands have a very high metabolic rate considering their size. Compared with Hereford cattle, their metabolism was 30% higher within the thermoneutral zone, and they excreted a far greater amount of urea in their urine (Taylor & Lyman 1967).

Activity patterns in Common Eland tend to vary depending on environmental factors and food availability (see, for example, Lewis 1978). In hot climates, such as Tsavo N. P., they may rest up in the shade all day feeding at night (Hillman 1979). On Loskop Dam N. R. in South Africa, Common Elands exhibited four main periods of activity during the day in winter, while in summer they moved and

fed in the morning, rested around mid-day, and fed again intensively in the late afternoon (Underwood 1975).

Although Common Elands, with their considerable bulk, usually move deliberately, they are capable of moving at great speed. When disturbed, they gallop, and jump high into the air, sometimes leaping over the backs of other animals. The gallop generally develops into a fast trot, which can be sustained for a considerable time. They are remarkably good at jumping, and can easily clear a two-metre-high obstacle.

There are a number of displays carried out by Common Eland ♂♂, involving the horns and the frontal brush of hair. These include vigorously rubbing the face in mud, particularly mud pats created by urine – either their own or from another animal. Adult ♂♂ also thrash vegetation with their horns, and break branches, and also rub their frontal brushes on tree stumps and broken branches. The effect of these behaviours is to change the appearance of the animal, with mud and/or vegetation being attached to the frontal brush and horns, and to accentuate the animal's smell. They appear to prefer 'smelly' substances for rubbing, such as aromatic shrubs and wet ash after grass fires (Hillman 1979).

Foraging and Food Common Elands are primarily browsers, though the degree to which grass forms an important component of the diet is debated. They have been classed as intermediate mixed feeders (Hofmann & Stewart 1972, Hofmann 1973), and Gagnon & Chew (2000), in their review of the diets of African bovids, considered them as browser–grazer intermediates taking as much as 50% grass. Analysis of rumen contents of shot animals in Kenya indicated that they were feeding on up to 60% grass in the wet season, but less than 10% during the dry season (Hillman 1979). Other studies (Lamprey 1963, Underwood 1975) have also indicated high proportions of grass in the diet, although Watson & Owen-Smith (2000) have highlighted the unreliability of these studies. Grass appears to be eaten in quantity only during the wet, summer months, and most stomachs examined from other times of the year contained only a small percentage of grass (Wilson 1969, Kerr *et al.* 1970, Scotcher 1982, Buys 1990, Watson & Owen-Smith 2000). In the study by Watson & Owen-Smith (2000), grass formed 45% of the diet in early Dec, but only 6–10% of the diet in other months of the early wet season. Studies involving

stable carbon isotope analyses of animals in both East Africa (including the Athi Plains region) and southern Africa indicate that although Common Elands may consume some grass, they have a significant component of browse in their diet and that few populations consume as much as 50% grass (Cerling *et al.* 2003, Sponheimer *et al.* 2003b; and see Wallington *et al.* 2007).

Diet usage has been associated with habitat use: Common Elands show a preference for bush habitat for the dry part of the year and for grassland in wet periods, although ♂♂ tend to use thicker bush areas than ♀♀ (Buys 1990, Fabricius & Mentis 1990). Common Elands introduced to Mountain Zebra N. P. in the Eastern Cape of South Africa showed similar habitat preferences, but habitat selection was unrelated to the availability of palatable grasses in the habitat (Watson & Owen-Smith 2000). Common Elands in Mountain Zebra N. P. have a diet comprising as much as 94% browse (Watson & Owen-Smith 2000), and have fared very well since their introduction. Watson & Owen-Smith (2002) have suggested this is because Common Elands have been able to select a diet sufficiently low in fibre content by eating young shoots of most woody species encountered and by consuming large proportions of palatable woody species with low fibre content.

In the wet season in Shinyanga, Tanzania, Common Elands were observed to eat herbs, particularly *Ipomaea* spp. and *Commellina africana* (Harrison 1936). During the dry winter months in southern Africa, they also eat dry fallen leaves. They also are known to eat fruits, such as those of *Sclerocarya caffra* and *Ximenia caffra*, and in the dry season have been known to eat the fleshy leaves of aloes (Harrison 1936, Wilson 1969).

Feeding takes place from ground level up to about 2 m. They use their lips, rather than tongue, to grasp food. Common Elands may strip the leaves off twigs by drawing them through their lips. The use of horns to break down high branches has been reported from some populations. Common Elands insert their horns on either side of a branch, and then twist until it breaks off or hangs down, when it can be reached (Skinner & Chimimba 2005). This behaviour was not observed in the Kitengela in Kenya or the Nyika Plateau in Malawi (Hillman 1979), but was seen in Common Elands confined in an enclosure with Camphor Bush *Tarchonanthus camphoratus* and in a wild population in E Zambia (Wilson 1969).

Common Eland *Tragelaphus oryx*.

Social and Reproductive Behaviour Common Elands have a very fluid social structure, and there appear to be no stable long-term relationships between individuals. The strong bonds between calves, and the ecological differences between ♂♂ and ♀♀, have resulted in an unusual social structure. Only one study has been carried out on the social organization of a large, naturally occurring, free-ranging Common Eland population – in the Kitengela Plains of Kenya (Hillman 1979, 1987); some aspects of this study differed from those of smaller enclosed populations such as that studied by Underwood (1973, 1975).

Group sizes are very variable, both between and within populations. In many areas the groups are usually small, but in some places and times groups in excess of 500 individuals may form. These have been reported from Hwange N. P., Zimbabwe (Wilson 1975), and from the south-western Kalahari, Botswana (C. Thouless pers. obs.). Groups show a high degree of flux, and adult Common Elands appear to move freely between groups. Association between individual animals is slight, rarely lasting more than a few days (Hillman 1987).

Common Elands are very seldom seen alone, and solitary animals are almost always the older 'grey' ♂♂. The most frequently observed herds are small groups of adult ♂♂, groups of ♀♀ (typically with less than ten individuals), or slightly larger mixed adult groups (usually of 10–20 individuals). However, groups containing juveniles in addition to adults are much larger, and those with calves larger still. Thus, these groups often include a large proportion of the total population in an area even though they are not the most frequently observed groups (Hillman 1979).

Male Common Elands appear to be more typical tragelaphines than the ♀♀. Males are most often seen in smaller, adult-only groups, particularly in all-male groups. Adult ♀♀ are mainly in calf-containing groups, and to a lesser extent in mixed all-adult groups. As a subadult animal matures it spends more time away from mixed groups, and with the small adult groups. Females then return to the nursery groups as they begin to calve, while ♂♂ continue to gravitate towards the very small all-male groups. These differences between the sexes are affected by their different feeding and ranging behaviour (see later).

Within large groups, young Common Elands are more closely associated with each other than with their mothers, and it is believed that this 'within-age-group' bond is the main reason why these large groups form. Most animals within a group are well spread out, with the exception of calves, which tend to form a tight 'creche'. Nursery groups are larger when environmental conditions are good, increasing to several hundred animals in grassland areas in times of high rainfall and good vegetation condition. This may be an anti-predation measure only possible during times of good food supply.

Common Elands in the KwaZulu-Natal Drakensberg display an unusual social organization, whereby they form large, mixed herds of up to 200 animals during summer (Dec/Jan), during which time breeding ♀♀ are mated by dominant ♂♂. From autumn (Mar) the large herds break up and they disperse widely in small groups of 4–10 animals, which may be of varying combinations of sexes and age classes. Shortly after the calves are born (Sep and Oct), the small groups start to join to form larger herds again (Scotcher 1982, Rowe-Rowe 1994).

There is no evidence of territoriality in Common Elands (Underwood 1973, 1975, Hillman 1979), and no evidence that faeces are used for marking. Urine and secretions from the frontal tuft may be used in some kind of marking. However, there is a dominance hierarchy within

Common Eland *Tragelaphus oryx* development of male colouring.

a population. A range of threats is used between individuals, including a threatening look, wiping the horns across the animal's own back, pointing the horns forward, and lunging with the horns (Hillman 1979). These threats usually result in the other animal moving away, and seldom escalate into more serious conflict. Sparring between the younger classes of ♂♂ is common. It involves the deliberate lowering of the heads, and tangling of the horns, followed by a pushing contest; this is often followed by the subordinate ♂ mounting its sparring partner or another nearby animal (Hillman 1979). Fighting is much less common, and results only when two old 'grey' ♂♂ are competing over ♀♀ in a group. Instead of deliberate tangling of the horns at close quarters, this involves charging together from a distance of 1–2 m, followed by pushing and manoeuvring to throw the other animal off balance. This can result in serious injuries. Apart from displays involving the males' frontal brush (described above under Adaptations), displays are in general not particularly 'ritualized' and are not unique to the Common Eland (Kiley-Worthington 1978).

Self-grooming is carried out regularly and involves scratching their bodies and faces on trees and other objects (or the front part of the body with a hindleg), and grooming with lips, teeth and tongues. Mutual grooming usually occurs between standing animals while chewing the cud, and involves the head and neck – parts of the body that cannot be reached by the animal itself. Mutual grooming only occurs between young or adult ♀♀.

Common Elands have a reputation as great wanderers; in some places this is thought to take the form of regular migrations, while in others there seem to be irregular movements, and some populations are believed to be more or less sedentary (such as those in SE Zimbabwe). The movements of free-ranging animals have only been studied in detail in the Athi-Kapiti area of Kenya, and in the south-west Kalahari of Botswana. Many populations are now confined within fenced areas, restricting what natural tendency there may be to move further. Hillman (1988b) studied the movements of Common Elands by repeated sightings of individually recognized individuals. Adult ♂♂ had home-ranges of approximately 30 km² while adult ♀♀ and juveniles had home-ranges of approximately 200 km². For both sexes most of these areas were used in the wet season; dry season ranges were considerably smaller. Male home-ranges were centred on areas of bush along gorges and drainage lines, or on forest edges. Females

Common Eland *Tragelaphus oryx* serial outlines of leap (from film).

and juveniles were found in similar areas in dry periods, but used areas of open grassland for longer periods in the wet seasons.

Common Eland movements have been studied in the south-western Kalahari, where they are largely confined to Kgalagadi Transfrontier Park, using radio-telemetry and satellite technology over a number of years (R. Brett, M. Knight, S. Makhabu, N. Nagafela & C. Thouless unpubl.). Aerial surveys in the park show that there is a tendency for the main concentrations of Common Elands to be in the bushy north-central part of the park in the wet season, with a surprising shift towards the drier sand dune areas of the south-west during the dry season (Verlinden 1998). In some dry years, such as 1985, this movement is particularly pronounced, and very large numbers of Common Elands may congregate in the south-west, including the fossil valley of the Nossob. Since animals fitted with collars were known never to go close to artificial watering holes, there must be some presently unknown ecological reason (and not a need for water) for this movement down the rainfall gradient in the dry season. Individual Common Elands in this area have very large home-ranges, averaging 8449 km² for ten ♀♀ tracked for at least one year, with a range of 1691–19,761 km² (minimum convex polygon).

Unlike other species, which tend to use a particular area for some time before moving on, Common Elands moved considerable distances on a daily basis. Typically they would be about 20 km distant from where they were 24 hours previously, and straight-line movements of up to 55 km were recorded over a 24-hour period. This pattern of movement was not dramatically affected by the onset of the rains. However, they do seek areas that have 'greened up' in response to the rains (R. Brett pers. comm.). In addition to migratory movements, Common Elands also make vertical movements in relation to food availability. In the KwaZulu–Natal Drakensberg, Common Elands spend most of their time in open grassland areas, particularly during the late spring and summer when the grass is green and nutritious. There is a vertical movement away from the central grassland area at the onset of the dry and cold winter, when green grass becomes unavailable. Animals then move into the montane forests and turn to browsing. The amplitude of movement ranges from between 5 and 40 km (Keep *et al.* 1972, Scotcher 1982, Rowe-Rowe 1983).

Flehmen plays an important part in courtship and is exhibited by all Common Elands from about three months old. However, it is most prominent in adult bulls, and they actively solicit urine from ♀♀ by pushing at the vulva. Females in oestrus are closely followed by the dominant bull in the herd, who chases and attacks less dominant ♂♂, and often lays his head on the female's rump or close to her side. Eventually she stands still to allow mounting, and intromission is brief.

Most births take place between 04:00h and 08:00h, peaking just at sunrise (Underwood 1979). The ♀ becomes restless then lies down on her side to give birth; calves, when born, are licked carefully before the afterbirth is eaten by the ♀. The calves struggle to a standing

position very soon after birth and can run within three or four hours. Calves lie up away from the herd for a few days. However, they soon join a herd and the great majority of calves are found in large nursery groups with other calves and juveniles. Within these groups the calves keep very close to each other in a calf crèche, and are often in close physical contact. Most of their activities take place in this group, and they leave it only to suck. Females visit the crèche to suckle their calves, calling as they approach. Usually the calf will run a short distance from the others to suck. Females do not suckle the calves of others, and sometimes even drive strange calves off. There is no evidence of a bond with the calf lasting beyond the time of weaning (Hillman 1979).

Common Elands are not very vocal. They make a deep gruff 'alarm' bark similar to that of the Bushbuck *Tragelaphus scriptus*. Females communicate with their calves using a series of repeated clicks; or by mooing and grunting or a combination of these (Underwood 1973, 1975). The calves respond by whimpering or moaning. At closer proximity the ♀ and calf exchange a weak bleat, and a similar noise is heard from adult ♂♂ during courtship (Hillman 1979). Adult bulls bellow in expressing their dominance or emit a belching grunt in repelling others from food. The larger adult 'grey' ♂♂ make a sharp clicking noise while walking as they lift each forefoot, which is audible up to several hundred metres away. Various sources have suggested the sound emanates from the hooves clicking together when the animal walks or from the carpal bones, but Posselt (1963), who worked with domesticated animals for many years, indicated it came from the knees, likely produced when a tendon slips over a carpal bone (Estes 1991a). Hillman (1979) suggested that the sound may act as an indication of the size and dominance of the animal. Subsequently, Bro-Jørgensen & Dabelsteen (2008) have shown that the dominant frequency of the knee-clicks in Common Eland is an honest signal of body size, reflecting both inter-individual variation and intra-individual changes over time.

Reproduction and Population Structure Common Elands are not strongly seasonal breeders, but there is a peak in calving during the early summer months of Aug–Nov in summer rainfall areas (Skinner & Van Zyl 1969, Skinner *et al.* 1974, Jeffery 1979,

Common Eland *Tragelaphus oryx* profile of male frontal 'brush'.

Common Eland *Tragelaphus oryx* frontal view of male 'brush'.

Underwood 1979, Scotcher 1982, Buys & Dott 1991), although in the south-western Kalahari the peak appeared to be in Nov (R. Brett pers. comm.). In Kenya, births occurred throughout the year, with a possible peak in Sep–Dec (Hillman 1979).

Oestrus occurs at 21–26 day intervals and lasts three days (Posselt 1963). Females typically have a postpartum oestrus (usually about two weeks following parturition; Posselt 1963) and this results in a shorter inter-calving interval. Jeffery (1979) reported the annual inter-calving interval for Common Elands in KwaZulu–Natal as ranging between 281 and 532 days ($n = 120$; mean = 373); the gestation period was around 273 days ($n = 53$; also recorded by Stainthorpe 1972). Usually only a single calf is born, with twins produced in about 2% of births in captivity (Zuckerman 1953). Recorded average birth weights of captive *T. o. oryx* calves include: 27 kg for ♂♂ ($n = 6$) and 25 kg for ♀♀ ($n = 9$) (Jeffery & Hanks 1981), and 30 kg ($n = 20$) and 26 kg ($n = 30$), respectively (Skinner & Van Zyl 1969; see also Stainthorpe 1972). Weaning takes place at about 4–5 months of age. The age at first conception is between 18 and 39 months (Hillman 1979), while ♂♂

do not breed under natural conditions at less than three or four years of age.

In the KwaZulu–Natal Drakensberg, sex ratio at birth is 1 : 1 (Stainthorpe 1972, Scotcher 1982); among adults, sex ratio has been given as 1 ♂ to 1.6–2.0 ♀♀ (Rowe-Rowe 1994). The sex ratio among adult Common Elands in the Athi–Kapiti population studied by Hillman (1979) was strongly female-based, with 1.9 ♀♀ to every ♂. Part of the reason for this may have been the tendency for adult ♂♂ to occur in smaller groups and in thicker vegetation, making them more vulnerable to predators. Rudnai (1974) found a male-to-female ratio of 9 : 1 in Lion *Panthera leo* kills in Nairobi N. P., Kenya. Over a five-year period in KwaZulu–Natal, mean sex and age structure comprised 15% adult ♂♂, 47% adult ♀♀, 12% yearlings and 26% calves (Scotcher 1982). Maximum longevity for wild Common Elands is 14–17 years, and captives have lived 25–26 years (Hillman 1979, Weigl 2005).

Annual calving rates in the Athi–Kapiti population were estimated to be 67% in 1972 and 68% in 1973 (Hillman 1979); those in southern Africa are higher at up to 90% (Buys & Dott 1991) to 95% (Scotcher 1982).

Predators, Parasites and Diseases Lions are the main predators of Common Elands throughout their shared range in Africa, but Common Elands seldom exceed 3% of their prey. This is probably because of the relatively low density of Common Elands compared with other prey species. Wright (1960) stated that Common Elands formed about 2% of Lion kills in S Kenya and C Tanzania, and Rudnai (1974) calculated that Lions killed approximately 2% of the Common Eland population annually in Nairobi N. P. Mitchell *et al.* (1965) found that Common Elands comprised 3% of Lion kills and 1% of African Wild Dog *Lycaon pictus* kills in Kafue N. P., Zambia. In a total of 817 African Wild Dog hunts recorded by Creel & Creel (2002) in Selous G. R., Common Elands were hunted on less than ten occasions. Young animals may rarely be taken by Cheetahs *Acinonyx jubatus*.

Starvation caused by drought can be a major cause of death, but Common Elands can sometimes escape its worst effects by moving long distances (Hillman & Hillman 1977). In the 1985 drought in the south-western Kalahari, it was estimated that 35% of the population died (Knight 1995a). In the KwaZulu–Natal Drakensberg, mortality was highest during Aug–Oct following the long, harsh winter, especially among calves and yearlings (Scotcher 1982).

Common Elands are described as bovine antelopes and it is reasonable to assume that the species, in its natural habitat, will contract similar viral, bacterial or parasitic infections as described for the cow in Africa, but the severity, symptoms and pathology will vary. For example, the species is susceptible to rinderpest (Thomas & Reid 1944, Robson *et al.* 1959), and, in an outbreak in Nairobi N. P. in 1996, there was an infection rate of 20% and mortality rate of 10% in Common Elands (Kock *et al.* 1999). Other important viruses such as foot and mouth disease have minimal impact on the species and they appear to be insignificant as carriers. They show no tendency to contract malignant catarrhal fever virus and their status as carriers of Rift Valley Fever and Lumpy Skin Disease is unknown. Bacterial diseases such as anthrax and parasitic diseases such as anaplasmosis have been reported in the species, and under certain conditions ticks and tick-borne diseases (e.g. theileriosis, transmitted by ticks of the

genus *Rhipicephalus*) can be significant; Rowe-Rowe (1994) notes that some introductions of Drakensberg animals to lowveld areas in KwaZulu–Natal failed because the animals succumbed to tick-borne diseases. The bacterium *Theileria taurotragi* is pathogenic and has caused deaths (Grootenhuys *et al.* 1980). Their resistance to trypanosomosis (which is transmitted by tsetse flies) is similar to other antelope. Except for the highly infectious diseases such as rinderpest and foot and mouth disease, the behaviour of the species (living in relatively small herds, timid and highly mobile) would reduce the chance of inter-specific infection. Once an individual in a herd contracts an infection, such as tuberculosis or anthrax, a high incidence is likely, since intra-specific dynamics are similar to cattle and buffalo.

Common Elands host a variety of ticks. Two animals taken in Central Province, Zambia, were host to seven species: *Amblyomma variegatum*, *Boophilus decoloratus*, *Rhipicephalus appendiculatus*, *R. evertsi*, *R. lunulatus*, *R. simus* and *R. supertritus* (Zieger *et al.* 1998b). Common Elands in Kruger N. P. harboured large numbers of *Amblyomma hebraeum*, but were also host to *B. decoloratus*, *Rhipicephalus appendiculatus*, *R. zambeziensis*, *R. evertsi* and *R. simus* (Horak *et al.* 1983c). In the Karoo of South Africa, Common Elands are good hosts for *Ixodes rubicundus* (Horak *et al.* 1987). Another animal examined post mortem was host to seven species of tick (*Amblyomma gemma*, *A. variegatum*, *Boophilus decoloratus*, *Rhipicephalus appendiculatus*, *R. evertsi*, *R. pulchellus* and *R. praeus*; Grootenhuys *et al.* 1980). Helminths recorded from Common Elands include three species of nematodes from Central Province of Zambia, *Cooperia rotundispiculum*, *Haemonchus contortus* and *Oesophagostomum* sp. (*H. contortus* is a blood-sucking parasite that can be pathogenic at even low levels of infection); the tapeworm *Moniezia benedeni* was also recorded (Zieger *et al.* 1998a). In Mountain Zebra N. P. and West Coast N. P., Boomker *et al.* (2000) recorded *Haemonchus mitchelli*, *Nematodirus spathiger*, *C. rotundispiculum* and *Bronchonema magna*.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Common Elands still occur over a large area of southern and eastern Africa, but their numbers and range have declined considerably. Their meat is highly prized and each animal provides a large quantity of meat, so they are particular targets of illegal hunters. In Botswana, their range has contracted over the last 20 years, so that now they are almost entirely confined to protected areas and to private lands. The Common Eland's habit of wandering over large areas may affect its future in ways that cannot be fully predicted. As available habitat declines, animals' ability to range widely is being reduced. It is possible that this will make populations that already tend to occur at low densities more vulnerable to environmental disturbances, such as drought and disease. However, Common Elands have been reintroduced to a number of game ranches and private ranchland in southern Africa (particularly South Africa), and this has done much to bolster numbers. In addition, animals have been introduced widely outside of their natural range, primarily to private ranches. For example, although their natural range in Namibia is restricted to the north-eastern parts, they now occur widely on game ranches in the southern and central parts (East 1999).

Important naturally occurring populations are protected in Omo N. P. (Ethiopia), Boma N. P. (Sudan), Serengeti N. P. (Tanzania), Kafue and North Luangwa National Parks (Zambia), Nyika N. P. (Malawi),

Etosha N. P. (Namibia), Kgalagadi Transfrontier Park (Botswana/South Africa) and Ukhahlamba-Drakensberg Park (South Africa). According to East (1999), approximately half the total population occurs in protected areas and 30% on private land. At present, the Common Eland is not in any immediate threat of extinction, and this situation is likely to continue as long as there are sufficient protected areas and private ranches to sustain viable populations.

Much has been written and published on the topic of domestication of Common Elands, which have been domesticated in Russia, Ukraine, England, Zimbabwe, South Africa and Kenya, for a number of perceived advantages: they provide a high yield of nutritious, 'long life', anti-bacterial milk, which has a high fat content; they can be readily tamed and herded; they can survive in arid regions unsuitable for cattle due to low water requirements; they have a long life expectancy in captivity; and they have a varied diet (Uspenskii & Saglanskii 1952, Posselt 1963, Skinner 1967, Lightfoot 1977, Lightfoot & Posselt 1977a, b). However, although captive animals reproduce successfully, management practices such as high food supplementation costs, confining them at night and herding them during the day are likely to negate their advantages over cattle in many environments (Hillman 1979).

HB (♀ ♀): 2270 (2200–2330) mm, n = 5

T (♂ ♂): 620 (570–720) mm, n = 5

T (♀ ♀): 530 (500–550) mm, n = 5

E (♂ ♂): 220 (210–240) mm, n = 5

E (♀ ♀): 210 (190–230) mm, n = 5

Sh. ht (♂ ♂): 1630 (1580–1790) mm, n = 7 (on the curve)

Sh. ht (♀ ♀): 1423 (1250–1530) mm, n = 7 (on the curve)

Sh. ht (♂ ♂): 1422 (1355–1500) mm, n = 6*

Sh. ht (♀ ♀): 1296 (1245–1330) mm, n = 6*

WT (♂ ♂): 494 (450–540) kg, n = 5

WT (♀ ♀): 344 (317–370) kg, n = 5

Athi-Kapiti Plains, Kenya (Hillman 1979)

*Serengeti, Tanzania (Sachs 1967), taken between the pegs

Common Elands in southern Africa generally are larger than the figures given here. Wilson (1969) gave the mean mass of five mature bulls as 604 kg (range 530–690), and ten ♀ ♀ had a mean weight of 445 kg (range 385–470). Skinner (1967) gave the mean mass of 19 mature bulls from bushveld areas as 650 kg (range 425–840). However, wild Common Elands from the KwaZulu–Natal Drakensberg are lighter, with mean adult masses of 453 kg (n = 17) for ♂ ♂ and 305 kg (n = 61) for ♀ ♀ (Scotcher 1982; and see Keep 1972). While weights of ♂ ♂ in Serengeti N. P. were similar to those of the Athi-Kapiti plains, weights of ♀ ♀ were considerably lower, with a range of 277–321 kg, and horns were shorter in both sexes (Sachs 1967)

Maximum recorded horn length is 118.4 cm for a pair of horns from Grootfontein, Namibia (Rowland Ward)

*including species-groups

The particular selection of antelope taxa that have been allocated to this subfamily has varied greatly over the years as has the relative ranking of Antilopinae within the family Bovidae: both remain subject to debate. In the treatment presented here, the Antilopinae embraces all the non-Bovinae bovids and these, colloquially referred to as antelopes, sheep and goats are held to share a common ancestry. A basal split between bovine and non-bovine taxa has long been recognized on morphological, physiological, ecological and behavioural criteria. Furthermore, a number of recent molecular studies have confirmed the reality of this most fundamental division of the family Bovidae (Hassanin & Douzery 1999, 2003, Matthee

Thomson's Gazelle *Eudorcas thomsonii* (frontal view).

& Robinson 1999a, Matthee & Davis 2001, Hassanin *et al.* 2012). Antilopinae, being the prior sub-familial name for all non-bovine antelopes, is therefore used in that broader sense, to the exclusion of nomenclatures that would restrict this rank to a smaller subset of gazelle-like species (Eisenberg 1981, Rebholz & Harley 1999, Hernández Fernández & Vrba 2005 and others), which are herein classed as the tribe Antilopini.

In distinguishing Antilopinae from Bovinae there are physiological differences that have a much broader, adaptive and biogeographic significance. Antilopinae regulate their body temperature by the advanced water-saving mechanism of nasal panting (although many of the Reduncini cool their bodies by sweating, this is almost certainly the secondary reversion of antelopes that have become tied to well-watered habitats). The thermoregulatory mechanism employed by all Bovini is the older, typically mammalian system of sweating, which is dependent upon continuous access to water and can be presumed to be the original condition of the main stem or founding bovid stock (for example, Gentry [1978] regarded the Asiatic boselaphines as the closest living descendants of early bovids and these bovines are also 'sweaters'). The development of 'nasal bellows' and nasal panting is possibly linked in some way with nasal 'whistling' calls that are uttered by all but the largest antelopes: the nasal areas of Bovinae are not modified for sound and they never utter any such calls. Antilopinae frequently have pedal glands (although individual species or groups have secondarily suppressed them), whereas all Bovinae lack these glands. Antilopinae also usually have facial glands (or their putative ancestors had typical glandular fossae on their skulls), although they are lacking in some species (e.g. Aepycerotini). Bovinae, on the other hand, lack facial

Bright's Gazelle *Nanger (granti)*
notata black and white design on
female udder.

glands (although some have glandular areas with a different histology). Antilopinae often have a single pair of nipples, although a number of tribes retain the older pattern of two inguinal pairs; all Bovinae have two pairs of nipples. Most Antilopinae have annulated horns (although a few conservative species have short, smooth spikes). Bovinae, by contrast, have smooth horns with a circular section or spiral ones (generated by differential growth rates at the base of the horn sheath).

The differences listed above (and more detailed physiological study will undoubtedly uncover more) are merely morphological markers for a fundamental divergence among early ancestral bovids. The more conservative species of Antilopinae are generally small or very small and are limited to small and stable home-ranges: the founding antilopine lineage would appear to have become adapted to hot and relatively dry conditions at an early date. Bovines, instead, generally have large or very large body sizes, often live nomadic lives in unstable habitats, and are adapted to wetter and generally cooler conditions.

The original divergence between Bovinae and Antilopinae probably involved a continental separation between the two ancestral stocks with the majority of some 24 species of Bovinae (sensu Grubb 2005) incontestably of Eurasian origin, whereas two-thirds (and by far the most diverse array) of about 120 Antilopinae are African. This separation broadly corresponds to adaptation by Bovinae to more temperate climates in the northern continents whereas stem Antilopinae adapted to the generally tropical climates of Africa. Recent molecular studies have shown that some small and very conservative species of African antelopes are basal Antilopinae, and their ecological and genetic distinctness implies speciation taking place very early on in the radiation of this group. The existence of small-bodied folivores among Australian macropods and Eurasian deer demonstrates that there are niches for small-bodied folivores in a wide range of habitats in all continents. Once such niches are occupied (and small African Antilopinae evolved more than 20 mya, probably at the beginning of the Miocene), the main selective pressure on them is to become better adapted to the specifics of their particular habitats, such as hot, arid thickets, cooler scrubs, equatorial forest or rocky hillsides. In particular, there is much to suggest that the smaller Antilopinae have made progressive improvements in physiological adaptation to local climates and environments. On the other hand, there has been much less pressure to alter the basic anatomical specifications incumbent on small size because selection has continued to favour a narrow range of body-sizes no less in Africa than other taxa in other continents. Although the common ancestor of all Antilopinae was likely to have

been a small animal, molecular evidence suggests that enlargement took place at a very early stage in antelope evolution (implied, for example, by the demonstration of basal status for the Impala *Aepyceros*; e.g. Georgiadis *et al.* 1990, Hassanin *et al.* 2012). The evolution of bigger bodies involves a chain of other adaptive changes and it seems significant that a majority of the more highly divergent, larger-bodied antelopes appear to derive from the same large-bodied basal lineage as the Impala. The survival of several very conservative basal lineages needs to be understood in this context of very narrow parameters for anatomical change in small antelopes, but much greater potential for elaboration in the larger lineages.

Taking account of dated antilopine fossils and the probable time needed to achieve today's very diverse radiation, Kingdon (1982) estimated a divergence date between Bovinae and Antilopinae of about 23 mya (Early Miocene). Using molecular clock techniques, Hassanin *et al.* (2012) have estimated that the split took place around 19.7 mya. Soon after arrival in Africa, antilopines began to adapt to local extremes of habitat and climate and sometime in the early or middle Miocene an early antilopine found its way back into Eurasia and this lineage gave rise to the predominantly Asiatic Caprini (Hassanin & Douzery 2003, Hernández Fernández & Vrba 2005).

Subdivisions within the Antilopinae remain problematic, but seven major groups have long been recognized: the duikers, Cephalophini; the dwarf antelopes, Neotragini; the kobs or waterbucks, Reduncini; the gazelline antelopes, Antilopini; sheep and goats, Caprini; horse-like antelopes, Hippotragini; and the alcelaphines, Alcelaphini. Each of these groups has radiated (in the case of caprines, into as many as 32 species). However, with the advent of molecular trees and clocks, a much more complex radiation has become apparent. The 'Neotragini', a grouping that formerly embraced some 13 or 14 species, and long suspected to represent contemporary survivors of a

basal type from which all the Antilopinae evolved (Kingdon 1982), has now been confirmed to be paraphyletic (Georgiadis *et al.* 1990, Gentry 1992, Gatesy *et al.* 1997, Matthee & Robinson 1999a, Rebholz & Harley 1999). Recognition that several living species occupy basal positions, and do not belong to any of the seven traditional subgroups of antilopinae, has suggested a bold biogeographic pattern that accords with much broader patterns of adaptation by Eurasian immigrant biota into Africa. New outlines for the primary and secondary radiations of Antilopinae are beginning to emerge and, in spite of numerous discrepancies between published trees, some convergent data (and opinions) are emerging, and these accord reasonably well with the following reconstruction of the antilopine adaptive radiation, based on a best fit between ecology, behaviour, palaeontology, anatomy and genetics. In spite of having been assembled before the advent of molecular trees or clocks, the first detailed effort to reconstruct this radiation (Kingdon 1982) conformed, to a surprising degree, with contemporary molecular findings.

Some mammalian immigrants entering Africa were able to do so because they were already very widespread, cosmopolitan species, but others, perhaps the majority, would have entered with ready-made ecological preferences compatible with the environments of (the usually rather narrow) corridor that permitted intercontinental exchange. Subject to the particular climatic cycle of their incursion,

whether cool or hot, the majority were probably adapted to dry but seasonally variable habitats. In the 27–23 million years since Africa regained contact with Eurasia there has been no true tropical forest connection and, barring some bat species, even the most adaptable mammals would have taken time to adapt to equatorial habitats. It is, therefore, significant that the three or four basal lineages that have emerged from molecular studies imply a very early adaptation by the first antelopes to three or four major adaptive niches.

The closest living approximation to the primary adaptive niche and to the relatively generalized anatomy of the earliest Antilopinae is the Cape Grysbok *Raphicerus melanotis*. Supposing then that the ancestral immigrant antilopine was a small, thicket-dwelling ruminant living under seasonally hot, but relatively dry, climates, a primary challenge for any such incoming group was to adapt to the more equatorial habitats of Africa, where diseases and all manner of environmental challenges awaited any immigrant. For small herbivores living on the forest floor, wetter climates meant higher, darker canopies and less ground-level foliage. Smaller bodies for an already small-sized antelope were the most likely outcome and the primitive dwarf antelope tribe Neotragini conforms with just such a prediction in terms of primarily equatorial distributions, sizes, habitats and feeding ecology. Genetically, neotragines are basal antelopes close to the primary radiation of all Antilopinae (Gatesy *et al.* 1997, Rebholz & Harley 1999, Hassanin *et al.* 2012), but they must have made their accommodation to tropical forest well after the first Antilopinae differentiated from ancestral Bovinae.

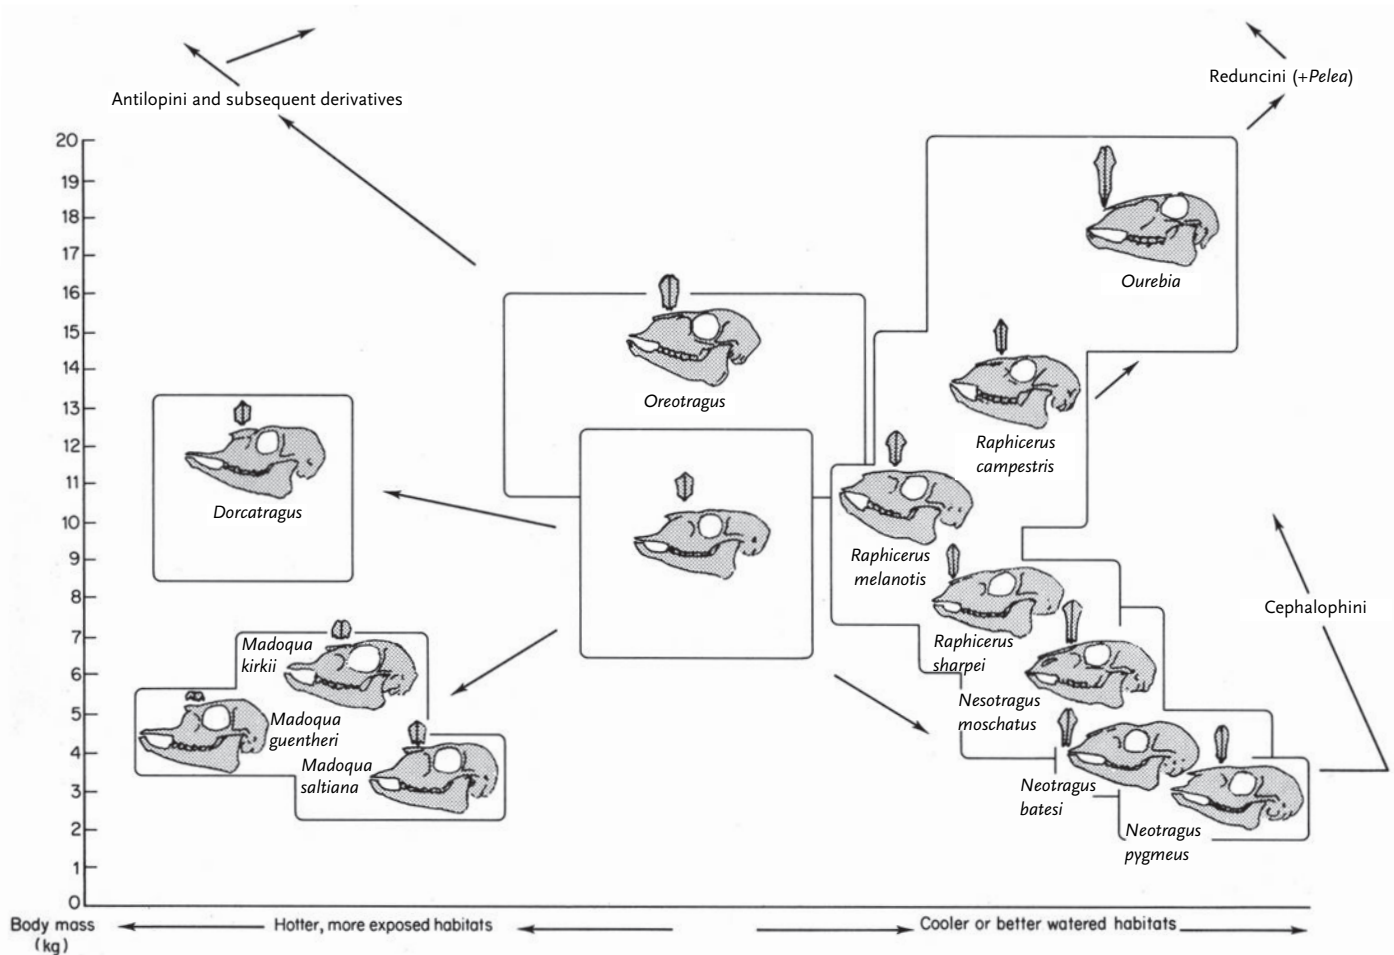

Because a very mountainous region lies immediately south of the main connection between Africa and Eurasia, many mammal immigrant groups can be shown to have made initial adaptations to the mountains of north-eastern Africa. Here, too, molecular trees agree in suggesting a basal position for the Klipspringer *Oreotragus oreotragus*, the only representative of the Oreotragini (and an archotypically Ethiopian species, although now widespread down the south-eastern half of Africa).

Another primary innovation would have been exploitation of more open, thicket-edge habitats. Here larger-bodied, longer-legged populations can be predicted because resources are more dispersed and predators at more of an advantage. Here, too, there is good conformity with molecular trees with a very early split accounting for the Impala as the only representative of a basal lineage, the Aepycerotini.

All molecular trees imply that the major antilopine lineages have each developed lineage-specific and identifiable adaptations to particular habitats, but none is consistent in distinguishing primary from secondary radiations. The primary ones suggested here are:

- 1 Small-bodied, thicket-dwelling lineage under dry climates typified by an early and conservative derivative, *Raphicerus*.
- 2 Dwarfed, forest-dwelling lineage typified by *Neotragus*.
- 3 Smallish, mountain- and rock-dwelling lineage typified by *Oreotragus*.
- 4 Larger, ecotone-dwelling lineage typified by *Aepyceros* (which might share common roots with either one of the two previous lineages or the common ancestor of all three).

It is suggested here that all other major antilopine tribes are likely derivative from one or other of the four primary lineages listed above, a conclusion that is broadly consistent with most recent molecular studies.

Body size and climate as major parameters in the radiation of antilopines. Some derivative lineages are indicated outside the 20 kg box.

Gazelline antelopes (Antilopini), as well as dik-diks (Madoquini) and kobs (Reduncini), can plausibly be derived from the earliest antilopine ancestral stock. The Beira *Dorcatragus megalotis* shows both morphological and molecular characteristics that suggest genetic links between *Raphicerus* and the gazelles and their kin. The dik-diks also relate to the same lineage on both counts. All these lineages show progressive physiological adaptation to heat-tolerance and water-conservation, but remain conservative in relation to a browsing, or 'concentrate-selector' diet (Hofmann 1973, 1989). The gazelles span a wide range of sizes and degrees of sociality, whereas dik-diks retain residential, territorial habits, small size and a highly selective fresh leaf diet.

The Reduncini have been proposed as a basal group (Hassanin & Douzery 2003), but they have a still unresolved relationship with two other antelopes. One, the Grey Rhebok *Pelea capreolus*, seems to represent the localized derivative from a very early reduncine. The other, the successful and widely distributed Oribi *Ourebia ourebi*, shares an odd mix of characteristics with the Steenbok *Raphicerus campestris* and members of the Reduncini. The Oribi's basal relationship to *Raphicerus* has been confirmed (Hernández Fernández & Vrba 2005), but its link to the Reduncini has been less widely accepted. However, its resemblances with reduncines are too numerous and too detailed to be easily explained by convergence. In direct opposition to the previous thicket-dwelling or arid-adapted Antilopini, reduncines and Oribi have become open valley grazers, relying, to a greater or lesser degree, on a very abundant but unstable food supply and continuous access to water.

This has involved very substantial physiological changes compared with most other Antilopinae, notably a water-dependent mode of cooling, by sweating, but also remarkable resistance to direct radiation from the sun. A conservative reliance on hiding, whether in dense grass, in swamps and water-logged areas or in large, dense herds, betrays the fact that Reduncini have very poor stamina and are, in that respect, conservative antilopines. They are most likely to be an early but secondary offshoot of *Raphicerus*-like Antilopini.

The duikers (Cephalophini) were once assumed to be among the most primitive of bovids (Estes 1974). In an early genetic analysis, Georgiadis *et al.* (1990) clustered duikers with the non-Bovinae but were unable to associate them with any other antilopine group (an outcome that could have suggested basal status). Duiker origins have proved remarkably opaque to molecular analysis and suggestions as to their closest affinities include Bovinae (Gentry 1992), somewhere in between Bovinae and Antilopinae (Jansen van Vuuren & Robinson 2001), Reduncini (Gatesy & Arcander 2000a, Kuznetsova *et al.* 2002) and Antilopini (Matthee & Davis 2001). They have been grouped in a variety of supposed clades; one permutation linked duikers with reduncines, hippotragines and alcelaphines (Gatesy & Arcander 2000b), another placed them with caprines, alcelaphines and hippotragines (Castresana 2001), and still other studies highlighted a close association with the Klipspringer (Hassanin & Douzery 1999, Matthee & Robinson 1999a, Hassanin *et al.* 2012). Thus, geneticists have invoked virtually every major bovid tribe as sister taxa for the Cephalophini!

Transformation of the head in three related antelopes. Reconstruction of ancestral African antelope skull.

Duikers share forest environments with the dwarf antelopes of the genus *Neotragus*, but differ in many aspects of their anatomy and behaviour (see Kingdon 1982). Instead of relying on scarce vegetation, duikers have enlarged their diet to include some animal matter, but rely to varying degrees on fallen fruits, seeds and other plant debris from the canopy. While their social systems show some adaptive variation, they tend to live spaced out in territories and they have not elaborated horns beyond short spikes. The radiation of duikers appears to originate in a very diminutive ancestor with the larger species being among the most recently evolved (Kingdon 1982, Jansen van Vuuren & Robinson 2001). This implies that duikers might represent a secondary radiation deriving from a diminutive *Neotragus*-like ancestor and the arguments for this origin were detailed in Kingdon (1982) and are summarized on p. 220. As for dating the divergence of duikers, the date of 6.3–5.6 mya (Jansen van Vuuren & Robinson 2001) seems rather late and extrapolated dates of 12.3–8.9 mya (Hassanin *et al.* 2012) might be possible.

The Klipspringer has no close genetic relatives (Gatesy *et al.* 1997, Matthee & Robinson 1999a, Rebholz & Harley 1999), and can be characterized as the single highly specialized survivor of a primary stem lineage. Some molecular resemblances with duikers have been observed and could suggest a phylogenetic connection, but the degree of specialization in the Klipspringer is so great that any very early relationships with later groups, whether duikers or caprines, are now obscured. What is clear is that this species

has paralleled some of the adaptations of goats and chamois and its early capture of the rocky mountain niche in Africa has probably discouraged the expansion of more recently evolved wild caprines into any habitats other than those in the Sahara and the highest reaches of Ethiopia. Whether these similarities are wholly convergent, or not, is debatable but some peculiarities of caprines would seem more likely to have found their roots in something like an early oreotragine or aepycerotine than in any other basal Antilopinae. Molecular analyses have suggested that the caprines might share ancestry with several superficially non-caprine antelopes and their common ancestor must have been very close to being a stem lineage. It is in this context that Aepycerotini is treated here as a true basal lineage that may be as close to Neotragini as it is to Oreotragini.

The Impala is the single surviving species of the Aepycerotini. At least one synthesis of recent studies (Hernández Fernández & Vrba 2005; and see Hassanin *et al.* 2012) has suggested that this apparently basal group has given rise to three major secondary radiations, the Caprini (over 30 spp.), the Hippotragini (7 spp.) and the Alcelaphini (6 spp.). Following Gentry (1978) and Vrba (1984), many authors have treated *Aepyceros* as a primitive alcelaphine, a relationship that has been shown to be only remotely true because it may be as closely related to the hippotragines and caprines. The more advanced members of the Caprini are late, mainly Asiatic and unquestionably belong to a secondary radiation. The Hippotragini are mostly arid-adapted grazers, living at low densities in arid or impoverished zones. The Alcelaphini, by contrast, are high density, ecotone/catenary grazers in open but less arid habitats. All three groups can be regarded as secondary radiations deriving from a single stem lineage. However, the living survivor of that stem lineage, the Impala, bears more resemblance to one of its derivatives, *Beatragus*, an alcelaphine, than it does to any of the horse antelopes or caprines.

The radiation of Antilopinae is summarized on p. 201 as a composite tree in which the dates of splits or branchings (as currently understood) are derived from disparate sources. The prolific radiation of antelopes has attracted several theoretically minded scientists, and the complex diversity of species has been broken down into various simpler categories (e.g. Schlosser 1904, Jarman 1974, Gagnon & Chew 2000). Vrba (1980) sought to explain their evolution and diversity by an 'effect hypothesis' in which less speciose 'generalists' were contrasted with speciose 'specialists'. Every such hypothesis has been hostage to the slender information-base that was available at the time of its inception, but recent field and laboratory studies have significantly improved our knowledge and potential for understanding one of the major radiations of large mammals in the world.

The current spectrum of Antilopinae embraces a diversity of folivorous, graminivorous (and frugivorous) niches and the ability of so many species to inhabit the same landscapes is based upon very precise foraging and digestive techniques. The details of many of these herbivorous strategies are described in the profiles that follow, but the likely development of antilopine niches can be summarized as follows.

The initial traits that distinguished early Antilopinae (in contrast to Bovinae) were small size, stable home-ranges and improved temperature and water regulation that allowed them to inhabit

Table 8. Diversification by habitat of Bovinae and Antilopinae.

drier habitats than their competitors. Their ruminant digestion ensured that they could maximize the extraction of nutrients and were therefore metabolically superior to the hyraxes, herbivorous macrotelids, rodents, chevrotains and larger non-bovid herbivores that preceded them. That dietary advantage is undoubtedly one reason for the success of antelopes in Africa.

Among Antilopinae, members of the tribe Antilopini have become 'gleaners' for high-quality foliage in arid or semi-arid habitats. Body sizes range from small to moderately large and the more advanced species are relatively social.

Among the most conservative of Antilopinae are the grysboks and Steenbok (*Raphicerini*), while most arid-adapted of all the small conservative tribes are the Madoquini.

The Reduncini have moved furthest from this pattern and have become specialists in exploiting tropical valley grasslands, often at very high densities. Body sizes range from medium to large.

Neotragini (*Neotragus* and *Nesotragus*) are minuscule and solitary gleaners of ground-level foliage in or on the edge of true forest.

The Cephalophini are also gleaners, but mainly of fallen fruit and have developed many interesting sub-strategies, some of which are directly dependent on the wasteful feeding habits of primates, hornbills and bats. They are mostly solitary and territorial and range from 3.5–80 kg.

The Alcelaphini have become large-bodied ecotone and catenary grazers, mostly in open habitats and tend to live at relatively high densities.

The Hippotragini are large-bodied antelopes that have adapted to arid habitats or impoverished zones and live, for the most part, at low densities.

Caprini are predominantly a late Asian radiation that evolved in direct competition with Cervidae. Many are adapted to extreme seasonal variations in diet and have colonized or recolonized mountain habitats in between glaciations. In Africa, a unique monospecific genus (*Ammotragus*) inhabits desert hills, mountains and plateaux and the slopes of desert valleys in the Sahara, and a second genus, the ibexes *Capra*, have colonized mountains down the western shores of the Red Sea as far as Ethiopia.

Antilopinae span a wide range of body sizes, weighing as little as 1.5 kg (Royal Antelope *Neotragus pygmaeus*) to 300 kg (several spp.). Many of the larger Antilopinae have interesting coat patterns that show increased contrast along the margins of limbs or those body regions that are typically counter-shaded in small cryptic species. Common origins for all antilopines are evident in similarities of patterning among members of different tribes.

Antelope skulls range from tiny compact structures with short spike horns, large preorbital fossae to enclose large facial glands above

Sketches of 'signal geometry' in three antilopine species; from left Beisa Oryx *Oryx beisa*, Sable Antelope *Hippotragus niger* and Waterbuck *Kobus ellipsiprymnus*. Note eye emphasis or eye suppression.

a short, finely pointed muzzle to heavy, elongated skulls surmounted by heavily reinforced horn cores. In spite of their diversity, horns share a basic structure among all Antilopinae: differential rates in the growth of horn sheaths and in the thickness of keratin deposits are the main determinant of species-specific horn shape and these have been explored in some detail in Kingdon (1982).

The teeth of Antilopinae have been widely misinterpreted, and in one of the first efforts to classify bovids, Schlosser (1904) broke down the wide variety of dental types into 'boodonts' (with a long shallowly rooted tooththrow with molar lobes and basal pillars) and 'aegodonts' (with hypsodont teeth, deeper teeth and roots in a shortened tooththrow). This classification became entrenched in the literature on bovids for nearly 80 years and was misleading because the teeth of different lineages responded to tougher diets and increased body size in very similar ways. Thus, larger-bodied, more hypsodont lineages, such as Hippotragini and Reduncini, became unnaturally clumped on the basis of similarities that are primarily due to larger size and more grass in the diet. A shift from softer diets in smaller antelopes to harder diets in larger

Oribi *Ourebia ourebi* myology.

Occlusal views of upper right tooththrows. (Upper left) Oribi *Ourebia ourebi* (grazer). (Upper right) Mountain Reedbuck *Redunca fulvorufula* (grazer). (Centre left) Cape Grysbok *Raphicerus melanotis* (generalized diet). (Centre right) Aders's Duiker *Cephalophus adersi* (partial frugivore). (Lower left) Suni *Nesotragus moschatus* ('concentrate selector'). (Lower right) Bates's Pygmy Antelope *Neotragus batesi* (strict folivore).

ones takes place *within* Antilopini, Reduncini and Caprini, while the largest antelopes in Reduncini, Hippotragini and Alcelaphini have all become hypsodont independently (Kingdon 1982). The transformation of a typical 'early' antilopine tooththrow can be illustrated by comparing the rows of *Raphicerus melanotis* with those of *Ourebia ourebi* (as an intermediate type) and *Redunca fulvorufula* (as a specialized grazer). The masticatory action of a browser slices rather than mills soft leaves and the tooththrow can be compared with the action of pinking shears or a long saw-edged blade: this functional morphology is most evident in the Neotragini. To turn a long narrow tooththrow over to a macerating action, milling edges across the face of each molar can be increased by simply folding enamel surfaces while the spaces in between the layers of crenellated enamel are bulked out with dentine filler. The combination of extra enamel folds and pillars, more soft dentine and greater depth and rooting both improves the milling action of mastication and lengthens the life of the tooth. The front end of the tooththrow declines in importance among grazers because a side-to-side or lateral mode of mastication, while more efficient for milling hard grasses, needs to be concentrated and needs maximum buttressing for the mechanical advantage to be optimal, hence the decline of premolar teeth in grazers.

All antelopes share longish, slender lower limbs and large-eyed, horned heads above longish necks but proportions differ greatly depending on size, habitat, range and other factors. The smaller, more conservative types have hunched postures and are able to make short, very fast dashes into cover but have no stamina. The larger, grazing species tend to have straight backs, longer legs, necks and faces and many are able to run far and fast, especially those living in open plains where there are numerous predators.

The social behaviour of antelopes has been widely studied, and has been extensively summarized in several works, in particular Estes (1991a). The more conservative species are territorial and residential, with male and female territories generally shared. Many of the larger species are highly mobile and land tenure and behaviour are varied (Jarman 1974). Antelopes occupy all the major habitats of Africa from forests to deserts and from sea level up into the high mountains.

Tribe NEOTRAGINI

Dwarf Antelopes

Neotragini Sclater & Thomas, 1894. The Book of Antelopes 1: 2.

Suni *Nesotragus moschatus*.

The tribe Neotragini has long been the acknowledged 'waste-paper basket' receptacle for a diverse collection of small-sized antelopes that resembled each other in their short straight horns, compact skulls, preorbital glands and slender legs. However, several recent studies have shown that the Neotragini, traditionally including *Dorcatragus*, *Madoqua*, *Neotragus*/*Nesotragus*, *Ourebia*, *Oreotragus* and *Raphicerus*, is paraphyletic (Georgiadis *et al.* 1990, Gentry 1992, Gatesy *et al.* 1997, Hassanin & Douzery 1999, Matthee & Robinson 1999a, Rebholz & Harley 1999). Since the differences between these antelope genera have long found acknowledgement, tribal status within Neotragini has herein contracted to only three former members of the Neotragini. All the rest have been allocated to other tribes.

With the advent of molecular science and the prospect of objective measures of genetic affinity, several former neotragines have been

shown to be more distantly related to one another than they are to other, less conservative groups. Furthermore, their resemblances can be interpreted as retentions indicative, in several instances, of their basal position in the radiation of African antelopes. The dwarf antelope genera *Neotragus* and *Nesotragus* constitute one such basal group, but more than one genetic study has associated the little Suni *Nesotragus moschatus* with another basal species, the much larger, rather gazelle-like Impala *Aepyceros melampus* (Georgiadis *et al.* 1990, Hassanin & Douzery 1999, Matthee & Robinson 1999a, Hassanin *et al.* 2012; but see Matthee & Davis 2001). This has served to emphasize the genetic isolation of *Neotragus* and has accelerated abandonment of the former 'waste-paper basket' category. Neotragini is here considered to embrace two species in the genus *Neotragus*, Bates's Pygmy Antelope *N. batesi* and the Royal Antelope *N. pygmaeus*, and the monospecific genus *Nesotragus* for the Suni.

LEFT: Suni *Nesotragus moschatus* adult male myology.
ABOVE: Suni *Nesotragus moschatus* skeleton.

Neotragine species resemble one another in retaining their attachment to a narrow range of forest types and retaining, too, a conservative dentition and feeding habits. It would seem likely that those primitive antelopes that succeeded in abandoning such dietary and ecological attachments became transformed and effectively founded entirely distinct lineages. The earliest precursors of such lineages were probably somewhat Suni-like or grysbok-like and the retention of a way of life typical of the earliest antelopes continues to give the behaviour and ecology of *Nesotragus* and *Raphicerus* a special interest. On a personal note, the decision, in 1964, to embark on a regional inventory of mammals and to entitle it *An Atlas of Evolution in Africa* (Kingdon 1971–1984) was my realization of the significant role that the then ‘Neotragine’ antelopes must have played in bovid evolution. Contemporary molecular studies have borne out the validity of that proposition. Other aspects of the contemporary biology of this tribe are discussed under *Neotragus* and *Nesotragus* and in the species profiles.

Jonathan Kingdon

GENUS *Neotragus* Dwarf Antelopes

Neotragus C. H. Smith, 1827. In: Griffith et al., Anim. Kingd. 5: 349.

Most recent classifications include the allopatric Royal Antelope *Neotragus pygmaeus*, Bates’s Pygmy Antelope *N. batesi* and the Suni *Nesotragus moschatus* in *Neotragus* (e.g. Grubb 2005). However, the species have been split into three genera in the past: *Neotragus sensu stricto* for the Royal Antelope, *Hylarnus* for Bates’s Pygmy Antelope and *Nesotragus* for the Suni. In this work, only *Neotragus* and *Nesotragus* are retained (see genus *Nesotragus* profile for further discussion). *Neotragus* in this sense only occurs in the rainforests of western and central Africa (including *N. pygmaeus* and *N. batesi*) – the only other small rainforest antelopes apart from duikers. The Suni, here retained in the genus *Nesotragus*, occupies a wider range of more mesic habitats in eastern Africa from Kenya south to KwaZulu–Natal.

Members of *Neotragus* are dwarf antelopes (shoulder height 20–33 cm, mass 1.4–3 kg), with relatively long hindlegs, and pelage

plain coloured or with traces of agouti-speckling or streaked. The rhinarium is naked. Preorbital glands open by a pore; inguinal and pedal glands are both present. There are no lateral hooves. Females have two pairs of nipples. Horns are present in the ♂ only, directed backward more or less in the plane of the forehead. They are short, thin and smooth in both Royal Antelope and Bates’s Pygmy Antelope (cf. the longer and stouter horns, with up to 20 well-marked annuli, in Suni).

In the skull, a premaxillo-maxillary vacuity is no more than a kink in the Royal Antelope, but vestigially present in Bates’s Pygmy Antelope. Apart from the Suni, this character is unknown in other extant bovids except the Impala *Aepyceros melampus* (Ansell 1972). Its possible evolutionary significance was discussed in Kingdon (1982) and elsewhere in this volume. A small ethmoid fissure is present in

Cartesian co-ordinates applied to the nasal maxilla and premaxilla of: Suni *Nesotragus moschatus* (left), Bates's Pygmy Antelope *Neotragus batesi* (centre), Royal Antelope *Neotragus pygmaeus* (right).

the Royal Antelope, but absent in Bates's Pygmy Antelope. In the former, the nasals are posteriorly narrow and pointed, whereas they are broadened and blunt in the latter species. There are large but shallow preorbital fossae accommodating the preorbital glands (larger in ♂♂). The incisiform teeth are small, the first incisors broad and others narrow. Upper milk canines are absent in Bates's Pygmy Antelope (and in the related Suni), but often present in the Royal Antelope. The cheekteeth are low-crowned, much like those of *Raphicerus*, and the premolars well developed.

Neotragus differs from *Raphicerus* in the shape of the muzzle, larger preorbital fossa, less upright horns, longer tail and presence of inguinal glands. Gene analysis suggests *Neotragus* and *Nesotragus* are distantly related to other traditional neotragine antelopes, and are probably better considered the only members of the tribe Neotragini (Hassanin & Douzery 1999, Matthee & Davis 2001), a course that is followed in this work.

Peter Grubb

Neotragus batesi BATES'S PYGMY ANTELOPE (DWARF ANTELOPE, BATES'S DWARF ANTELOPE)

Fr. Antilope de Bates; Ger. Batesbockchen

Neotragus batesi de Winton, 1903. Proc. Zool. Soc. Lond. 1: 192. 'Efulen, Bulu Country, Kamarun [Cameroon], 1500 ft [457 m] above the sea'.

Bates's Pygmy Antelope *Neotragus batesi*.

Upper-right tooththrow of Bates's Pygmy Antelope *Neotragus batesi*.

Taxonomy Polytypic species with two recognized subspecies. Originally designated as a monospecific genus, *Hylarnus* (De Winton 1903), it has also been allocated to the subgenus *Nesotragus* (Haltenorth 1963), but *Nesotragus* is here retained only for the Suni *N. moschatus*. Synonyms: *harrisoni*. Chromosome number: not known.

Description Very small antelope, with short muzzle, large eyes and long thin legs. Pelage sleek and fine mahogany-brown, darker on back, crown and forehead. White spots at the base of ears; chin and throat white. Young may have a cream spot above eye. Preorbital glands large, especially in ♂♂, round and not invaginated. Chest, belly, inner parts of upper forelegs and hindlegs, front fetlocks white. Lateral hooves rudimentary. Pedal glands are present. Tail short, inconspicuous brown, lighter below. Females are 6% larger (total length) and 21% heavier than ♂♂. Narrow folivorous teeth.

Horns present in ♂ only, small, smooth, weakly ringed at base, parallel to forehead line, tips slightly converging. In contrast to the Royal Antelope *N. pygmaeus* and the Suni, the ethmoid fissure is absent in Bates's Pygmy Antelope. There is a vestigial hiatus between the maxillary and intermaxillary (the premaxillo-maxillary vacuity, as in the Suni), and there is no anteorbital vacuity.

Geographic Variation

N. b. batesi: SE Nigeria, east of Niger R. to Cross R., and S Cameroon, Equatorial Guinea, Gabon, SW Central African Republic and Congo.

N. b. harrisoni: NE DR Congo and SW Uganda. More contrasted pelage, with more white on the legs (see Thomas 1906).

Bates's Pygmy Antelope *Neotragus batesi* skulls, adult male above, subadult below.

Similar Species

Neotragus pygmaeus. Only occur in forests west of Dahomey Gap. Smaller in size, more reddish pelage, rufous collar thinner than in Bates's Pygmy Antelope; lateral hooves absent.

Nesotragus moschatus. Only occur in forests and thickets east and south of the Eastern Rift Valley. Larger in size, freckled dark brown pelage; horns of ♂ longer, finely annulated and slightly uprising; lateral hooves absent.

Philantomba monticola. Broadly sympatric. Larger in size and of more stocky build, grey or grey-brown.

Distribution Endemic to Africa. Patchily distributed in moist lowland forest in three disjunct regions: SE Nigeria, east of the Niger R. to the Cross R.; S and SE Cameroon (south of the Sanaga R.) to SW Central African Republic (west of the Sangha R.), Gabon, and NW and SW Congo; and NE DR Congo, north and east of the Congo–Lualaba, extending marginally into SW Uganda (East 1999). The gap in distribution may be due to ancient dry corridors during past glacial periods. Today, swamp forests from N Congo and DR Congo may constitute a barrier of unfavourable habitat.

Habitat Bates's Pygmy Antelopes inhabit moist lowland forest. They prefer dense, low undergrowth along rivers, tree falls within mature forests, areas regenerating after logging or cultivation, road sides, village-gardens and plantations where they exploit patches of high-quality forage growing where light reaches soil (Dragesco *et al.* 1979, Feer 1979, Hart 1985). According to Mbuti hunters of NE DR Congo, they avoid damp, swampy habitats (Carpaneto & Germi 1989).

In NE Gabon and S Cameroon, they apparently are excluded by drought during dry seasons (expressed as rainfall minima in the driest season, 25–50 mm per month) (Feer 1979).

Abundance Locally very abundant within optimal habitat such as in cocoa or cocoa plantations mixed with secondary forest in NE Gabon (35–75/km²; Feer 1979); uncommon in the Lopé N. P. in

Gabon (White 1994, P. Henschel pers. comm.). Densities over more extensive areas of forest are 1.5–2.2/km² (Hart, J. A. *et al.* 1996, Fa & Purvis 1997). In forests of S Central African Republic, encounters of Bates's Pygmy Antelopes during net hunts represent only 0.2% of total artiodactyls (Noss 1999). In the Ituri Forest, NE DR Congo, it represented 3.6% of the captures by nets (Carpaneto & Germi 1989). Here, estimated densities in mature forest are similar to those in regrowth (Wilkie & Finn 1990). Despite higher hunting pressure, encounter rates within 14 km from a village in Dja Reserve in Cameroon were higher than at distances further away (Muchaal & Ngandjui 1999). East (1999) estimated a total population size of about 220,000 individuals.

Adaptations Typically slow-moving while foraging, with a high-stepping and hesitant gait in dense vegetation. Ratio of free height under chest to shoulder height is higher than for duikers (tribe Cephalophini). When alarmed may freeze a long time before jumping for cover. Flees quickly at short distances, occasionally with barking. Active both at night and day, with rests around mid-day and in the early and middle evening. In cultivated zones, animals rest in the densest areas by day and relatively more open areas by night. At night they move 51% less in open habitats (generally rich in food) than in other habitats. Lactating ♀♀ and young prefer dense protective habitats (Feer 1979).

Foraging and Food Folivorous; classed as browsers by Gagnon & Chew (2000) in a comprehensive review of dietary preferences in African Bovidae. Bates's Pygmy Antelopes delicately pluck leaves, buds and shoots, choosing small young items, but also consuming very large leaves (e.g. *Dioscorea*, *Calocasia*). They browse selectively on more than 200 species in cultivated areas in Gabon (Feer 1979), with recorded preferences for species in the genera *Brillantaisia*, *Momordica*, *Phaulopsis*, *Cyathula* and cultivars, notably sweet potatoes, peanuts and peppers. Near villages, they adapt their home-ranges

to the seasonal rotation of clearings and growth of small plants; on average, half of their home-range is composed of dense herbaceous strata (Feer 1979). Their diet in deep forest is poorly known. They consume four species of forest fruit and various leaves according to Mbuti Swa from the Ituri Forest (Carpaneto & Germe 1989).

Cerling *et al.* (2003) found that three different teeth taken from a single individual from the Ituri Forest had the most ^{13}C -depleted bioapatite values from the more than 1000 extant mammals they had analysed, indicating that the species effectively has no capacity to survive on coarse grass or leaf diets.

Social and Reproductive Behaviour Most often solitary (61% of observations, Feer 1979); two or more adults are rarely seen within short distance (<50 m) of each other. Adult ♂♂ seem to occupy exclusive home-ranges and mark the tips of browsed plants with black preorbital secretion; ♀♀ do not mark. Middens or ritualized defecation were not observed. Male home-ranges (2–4 ha) include several overlapping female home-ranges. Short nasal moans are a common contact call.

Reproduction and Population Structure Histology suggests sexual maturity is attained at 8–18 months for ♂♂ and ca. 16 months for ♀♀. Reproduction occurs all year round, although births peak twice a year at the end of the wet seasons. Around 80% of subadult (16–26 months old) and adult ♀♀ are pregnant. Newborn weight is ca. 300 g. Weaning takes place during the favourable following wet season (Dubost & Feer 1992). In Gabon, a sample of 103 individuals from a weakly hunted population comprised 47% adults. Males accounted for 42% of adults. Mortality of subadult ♀♀ is higher than in ♂♂ (Feer 1979).

Predators, Parasites and Diseases In the Ituri Forest, Bates's Pygmy Antelopes represent 2.1% of prey items in scats of Leopards *Panthera pardus* and 4.0% of African Golden Cats *Profelis aurata* (total felids 2.7%, Hart, J. A. *et al.* 1996). Mbuti hunters report predation by African Golden Cats and Crowned Eagles *Stephanoaetus coronatus* (Carpaneto & Germe 1989). They are fragile and die from stress after prolonged chases. Very little information is available on diseases and parasites; Durette-Desset (1973) recorded a new species of filarial parasite (*Setaria pujoli*) from this species in Cameroon.

Conservation IUCN Category: Least Concern. CITES: Not listed.

The status of Bates's Pygmy Antelope should remain stable wherever forests remain sparsely settled. However, increasing pressures of hunting, logging and clearing for cultivation in central African forests represent a serious threat. Despite the ability of the species to use disturbed habitat, its future survival may be increasingly dependent on protected areas. At present the protected areas within which it is common, including Dja Reserve (Cameroon), Dzanga-Sangha Special Reserve (Central African Republic), Odzala N. P. (Congo Republic), Monte Alén N. P. (Equatorial Guinea) and Kahuzi-Biega N. P. and

Bates's Pygmy Antelope *Neotragus batesi*.

Okapi Faunal Reserve (DR Congo), receive very unequal levels of protection and management. Consumption in the rural areas around Kisangani (DR Congo) represents 8% of total artiodactyls and 0.9% of total game, but Bates's Pygmy Antelopes are very rare in the urban bushmeat market (Colyn *et al.* 1987). They are totally absent from the market of Makokou (Gabon) (Lahm 1993, F. Feer pers. obs.) at 70 km from the species' distribution limit, and in five markets visited across the country in 2004, Bates's Pygmy Antelopes made up only 285 kg in terms of biomass (Projet Gibier Gabon pers. comm.). Consumption is limited by various food restrictions and taboos in NE Gabon (F. Feer pers. obs.) and DR Congo (Carpaneto & Germe 1989).

Measurements

Neotragus batesi

HB (♂♂): 513 (470–560) mm, n = 25

HB (♀♀): 548 (480–580) mm, n = 33

T (♂♂): 88 (70–100) mm, n = 25

T (♀♀): 88 (70–100) mm, n = 33

HF c.u. (♂♂): 147 (130–160) mm, n = 25

HF c.u. (♀♀): 152 (140–170) mm, n = 39

E (♂♂): 47 (40–50) mm, n = 23

E (♀♀): 48 (40–50) mm, n = 36

Sh. ht (♂♂): 306 (280–310) mm, n = 24

Sh. ht (♀♀): 318 (280–335) mm, n = 33

WT (♂♂): 2.19 (1.8–2.6) kg, n = 26

WT (♀♀): 2.76 (1.9–3.4) kg, n = 30

Gabon (Feer 1979, F. Feer pers. obs.)

Record horn length is 4.4 cm for a pair of horns from Uganda (Rowland Ward)

***Neotragus pygmaeus* ROYAL ANTELOPE**

Fr. Antilope royale; Ger. Kleinstbockchen

Neotragus pygmaeus (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 69. 'Habitat in Guinea, India'; restricted to 'Guinea' (West Africa) by Thomas (1911: 152).

Royal Antelope *Neotragus pygmaeus*.

The common name derives from Bosman (1704), who reported that people in the Gold Coast (Ghana) called it 'The King of Antelopes'. He failed to note whether the name was symbolic, gastronomic or ironic, but stories about the guile of the Royal Antelope are widespread in West Africa. In Sierra Leone it is known as 'the cunning rabbit' in stories where it sometimes plays an equivalent role to America's 'Brer Rabbit' (where such stories might have been transplanted from West Africa).

Taxonomy Monotypic. See Grubb (2005) for detailed discussion regarding former misidentification of this species as a tragulid. *Neotragus pygmeus* is an incorrect original spelling. Synonyms: *perpusillus*, *pygmeus*, *regius*, *spinigera*. Chromosome number: $2n = 36$ (K. Benirschke *in litt.*).

Description A tiny antelope, with very thin, long legs, large eyes, relatively small, flesh-coloured ears and a diminutive tail with white underside. Pelage is fine and soft, reddish or golden-brown and particularly red on the rump; darker brown on upper back, crown and forehead. Sides of face sandy-red; white spots at the base and upper margins of ears. Lower jaw, throat 'bib' and chest are white; underparts and inside of limbs whitish. Preorbital glands are small, both relatively and absolutely (see Kühn 1976 for further information on these glands). Lateral hooves absent or vestigial. Pedal glands are present. Sexes of similar size, but ♀♀ are marginally larger and heavier than ♂♂.

Tiny conical horns, in ♂♂ only, follow the line of the nose and forehead and may be concealed by crest hair. Unlike other *Neotragus* species, the hiatus between the maxillary and intermaxillary (the premaxillo-maxillary vacuity) is filled by what appears to be a phylogenetic migration of the maxilla, premaxilla and nasal. The anterior, premolar section of the toothrow is reduced and the masseter and its attachments are proportionally smaller than in

Neotragus pygmaeus

Neotragus batesi. Upper milk canines are often present in the dentition (Dekeyser & Derivot 1956).

Geographic Variation None.

Similar Species

Neotragus batesi. Only occur in forests east of Niger R. Slightly larger in size, longer legged, less brightly coloured.

Philantomba maxwelli. Sympatric. Larger in size and more strongly built; grey or greyish-brown.

Distribution Endemic to Africa, ranging in lowland rainforest (and marginally in the forest-savanna mosaic to the north) from SW Guinea (the Kounounkan Massif perhaps representing the westerly known limit; see Barnett *et al.* 1996; Barnett & Prangley 1997), Sierra Leone, Liberia, SE Guinea, Côte d'Ivoire, to the Volta R., Ghana (Grubb *et al.* 1998, East 1999). The species has apparently been recorded from the forests east of the Volta R. in NE Ghana, where R. Jamieson observed it on sale in the Binaba market, but this record remains questionable (Grubb *et al.* 1998); it was also thought possible that it may occur in Digya N. P., east of the Volta (Ankudey & Ofori-Frimpong 1990), but this seems doubtful. Fischer *et al.* (2002) reported what they considered to be reliable observations of the tracks of Royal Antelopes in Comoé N. P. in NE Côte d'Ivoire. Records of the species' presence in Cameroon (Jeannin 1936) refer to Bates's Pygmy Antelope *N. batesi*, and records of the species' presence in Togo (Happold 1973b) are also in error.

Lateral and palatal views of skull of Royal Antelope *Neotragus pygmaeus*.

Habitat Royal Antelopes inhabit moist lowland forest and secondary vegetation habitats, and can adapt well to the farm bush regrowth that follows forest clearance. In Sierra Leone, where the species is encountered more commonly in logged forest with some undergrowth than in primary forest, it has been reported mainly caught by hunters by means of duiker snares set in fences round farms and in nets when swamps and bush areas are netted and subjected to game drives during the dry season (Grubb *et al.* 1998). It is commonly reported from cultivation, both small-scale and commercial, and grassy or leafy road verges. It prefers dense undergrowth at ground level along forest edges and clearings, both within the moist forest belt and in forest galleries in drier forest–savanna mosaics. The animals seek out areas where sunlight reaches the soil and generates fresh green growth. Because it is essentially dependent on very fresh green growth at ground level and because it becomes vulnerable to predators when exposed, open areas under the closed canopy of high forests do not support Royal Antelopes. They are able to persist in relatively small forest fragments.

Abundance Said to be locally abundant, notably in Côte d'Ivoire where it is common in bushmeat markets. East (1999) has suggested an extrapolated density range of 0.2–2.0/km² and estimated the total population at a little over 60,000, which he acknowledged was likely to be a substantial underestimate. In the main bushmeat market in Kumasi, Ghana, Wilson (2001) found an annual sale of about 1200 carcasses of Royal Antelopes. He also found that most animals are consumed locally so the carcasses reaching urban markets are less than half of the hunters' actual catch. For such an off-take to be sustainable, which seems likely, East's upper estimate of 2.0/km² is certainly a minimum realistic density.

Adaptations Exceptional alertness to danger is the dominant characteristic of this species and it is typically extremely cautious whenever exposed. As with other small antelopes, it has a high-stepping and hesitant gait, freezing at the slightest alarm. It 'scurries', fast, with head down, when mildly disturbed but can dash through cover very fast when necessary. Its disproportionately large hindquarters power leaps and bounds that assist a quick escape.

Such a very small antelope is prey to a very wide range of predators and its adaptations to such vulnerability could, perhaps,

have helped deter scientists from investigating the world's smallest ruminant. Considering our need to thoroughly understand the central process governing the productivity of our three main domesticates (cattle, sheep and goats) it is obvious that rumination in the smallest bovid should offer special insights into rumen physiology. The little that is known suggests that the Royal Antelope has adapted its behaviour and physiology to the special problems of extracting nutrients from the tiny 200–250 g fermenting vat that is its stomach. In ruminants, the products of fermentation must be absorbed while, at the same time, pH levels remain tolerable for the micro-organisms in the rumen and for the tissues of the rumen itself. Nagy (1970) correlated lowering of pH in the rumen with increases in lactose-fermenting organisms so it would be interesting to know what role these organisms play in the Royal Antelope. Hofmann (1973) has noted that ruminoreticula of small capacity compensate for their reduced volume by enlarging their absorptive surface enormously while at the same time increasing the rapidity of fermentation, thus removing fermentation products before they damage the system. Extrapolating from Hofmann's studies of other small ruminants it could be predicted that the Royal Antelope would select highly digestible foods and that it would keep augmenting its food intake. In spite of grossly inadequate data, both predictions are tentatively borne out.

Although it is often described as nocturnal, casual sightings in Tai N. P. (e.g. see Hoppe-Dominik *et al.* 2011) are consistent with other sightings, hunters' observations and the behaviour of captives that suggest the Royal Antelope is intermittently active both at night and during the day.

Unlike other members of the Neotragini this species has significantly smaller preorbital glands. As these glands are associated with the marking of home-ranges or territories their reduction implies that home-ranges are not marked or defended in the same way or with the same intensity as other small antelopes. On the other hand, the area of the skull devoted to olfaction is relatively greater than it is in Bates's Pygmy Antelope or the Suni *Nesotragus moschatus*, both of which have compressed narrow snouts, especially towards the snout. Effectively, the Royal Antelope has enlarged and elongated its muzzle *vis à vis* its relatives. However, it is unclear whether this is primarily linked to efficient plucking of foliage or part of an improvement in olfactory performance.

Foraging and Food Folivorous, but precise preferences currently unknown. Royal Antelopes have a muzzle that is longer, with relatively broader lips, but smaller mouth and smaller chewing muscles than in Bates's Pygmy Antelope. There are also constraints on the digestibility of their food, so that any growth that is at all lignified must be excluded or rejected. This combination suggests that this species is peculiarly dependent on physically soft, nutritionally digestible leaves, buds and shoots. Because canopies, high or low, are constantly changing in its habitat it is likely that the frequent 'shading out' of its food supply makes fresh growth effectively unpredictable and ephemeral in its distribution. Even for the very small quantities that are eaten, foraging is probably opportunistic and involves movement over areas that are not intimately known. Animals are snared on bush farms where they are attracted to the new foliage of crops such as yams, sweet potatoes, amaranthus and peppers. It is possible that they have adapted to the

particular cultivation cycles of forest edge farms and to the growth of so-called weeds along road verges.

Social and Reproductive Behaviour Commonly seen singly, but their ranging and territorial behaviour is unknown. Unlike other small antelopes they have not been reported to mark plants with preorbital secretions (which is interesting in the light of this species having greatly reduced preorbital glands). Contact behaviour between individuals has not been studied and ritualized defecation has yet to be noted. Owen (1973) described a hand-raised captive making an audible contact call.

Reproduction and Population Structure A remarkably consistent harvest of these antelopes throughout the year suggests that they do not have a marked breeding season. Consistently high catches over many years suggest a high level of fecundity but nothing has been recorded about their population structure. A single young is born, and there are no records of twins in the literature. A young captive observed by Owen (1973) began ruminating at four months of age. Other information on breeding is not available. Longevity in captivity is 6 years and 8 months (Jones 1993).

Predators, Parasites and Diseases Leopards *Panthera pardus*, African Golden Cats *Profelis aurata* and Servals *Leptailurus serval* are now rare over much of their range and snaring, netting, trapping, hunting with dogs and guns represent the main sources of mortality. Crowned Eagles *Stephanoaetus coronatus* probably take them on occasion. Ntiemoa-Baidu *et al.* (2005) examined 58 animals in Ghana and recorded the following ixodid tick species: *Haemaphysalis*

parvata, *I. muniensis*, *I. moreli*, *I. aulacodi*, *Rhipicephalus ziemanni* and *R. simpsoni*. Diseases are unknown.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Still relatively widespread, even within its small range, and somewhat abundant in some parts. Their ability to survive well even in secondary habitats has helped it fare better than other species in the face of habitat loss, and they are present in several protected areas including Gola N. P. and Tiwai Island (Sierra Leone), Tai N. P. (Côte d'Ivoire) and Kakum N. P. (Ghana). However, they are at risk from bushmeat hunting, and high prices are sometimes paid for the meat of this species in urban markets. East (1999) reported that local taboos on hunting or consumption of Royal Antelope still operate in Liberia, where the species is regarded as the epitome of cunning by rural people.

Measurements

Neotragus pygmaeus

HB: 430 mm

T: 50 mm

Sh. ht: 260 mm

WT: 2.4 kg

Captivity (Owen 1973)

Record horn length is 3.4 cm for a pair of horns from Totota, Liberia (Rowland Ward)

GENUS *Nesotragus*

Suni

Nesotragus von Dueben, 1846. In: Sundevall, C. J. Ofvers. Ventensk Akad. Forh. Stockholm III.

In most recent nomenclatures, the Suni *Nesotragus moschatus* is included, together with the Royal Antelope *Neotragus pygmaeus* and Bates' Pygmy Antelope *N. batesi*, in *Neotragus* (see e.g. Ansell 1972, Meester *et al.* 1986, Grubb 2005). In this work we provisionally retain the older practice of treating the Suni as a monospecific genus (see Allen 1939, Roberts 1951, Ellerman *et al.* 1953).

The principal external distinctions include: longish male horns (up to 13 cm) with 13 or more irregular ridges on the basal half or three-quarters of the horns; a longish muzzle in which there is an ethmoid vacuity between the maxilla and premaxilla (only vestigially present in Bates's Pygmy Antelope, and otherwise unknown in any other bovid, except the Impala *Aepyceros melampus*; Ansell 1972); the rear of the bony palate extends beyond the back end of the toothrow; processes on the lower anterior surfaces of the basioccipitals; exceptionally large preorbital glands and fossae; and well-developed premolars.

Further subdivision of *Neotragus*, or a return to older nomenclature, is still conceivable; for example, the retention of *Hylarnus* for *N. batesi* might be justified were molecular studies able to demonstrate a great age for the divergences within the three members of the tribe Neotragini. *Nesotragus moschatus* has been shown to be a basal member

Suni *Nesotragus moschatus*.

of the Antilopinae (Hassanin & Douzery 1999, Rebholz & Harley 1999, Matthee & Robinson 1999a) and while its close relationship with *Neotragus* is not contested there are several anatomical details that suggest that both *Neotragus batesi* and *Neotragus pygmaeus* are derived species from a more *Nesotragus*-like ancestor. Roberts (1951)

thought that the three forms not only deserved generic status, but even thought that they could be considered representative of different subfamilies!

The likelihood that *Nesotragus* is the most conservative of the Neotragini finds support in an examination of the nasal region. Both species of *Neotragus* have diminished premolars, shortened maxilla and elongated nasals. Feeding on tough foods, including roots, in the drier forests and thickets of eastern Africa, the Suni's retention of robust premolar and molar teeth would not only be favoured by selection; it almost certainly resembles more closely the condition of an early, thicket-dwelling ancestral type.

Nesotragus moschatus SUNI

Fr. Antilope musquée; Ger. Moschusboeckchen

Jonathan Kingdon

Nesotragus moschatus (von Dueben, 1846). In: Sundevall, Ofv. K. svenska Vet.-Akad. Forhandl., Stockholm 3 (7): 221. 'in Chapani (Anglis French island) occisa insula prope Zanzibar in Lat. Austr. 6° 9', Long. Orient. 39° 14' a Greenwich sita, fructibus dense tecta et fonte irrigata' (Tanzania, Chapani I., 3 km from Zanzibar).

Suni *Nesotragus moschatus*.

The common name is derived either from the Kikuyu name for the species, *kasuni*, or from the *suni* of the related Wachagga people, or from the *suni* of a related tongue, Kichagga.

Taxonomy Several earlier authors, including Allen (1939), Roberts (1951) and Ellerman *et al.* (1953), included the Suni in the monotypic genus *Nesotragus*, although the species has traditionally been classified as one of three dwarf antelopes in the genus *Neotragus* (e.g. Ansell 1972, Grubb 2005). As outlined under the genus profile, we retain the species in genus *Nesotragus*. Synonyms: *akeleyi*, *deserticola*, *kirchenpaueri*, *livingstonianus*, *zanzibaricus*, *zuluensis*. The chromosome number of southern African populations is $2n = 56$ (Robinson *et al.* 1997). Kingswood *et al.* (1998a) also reported a diploid number

In invading the equatorial rainforests, *Neotragus batesi* and *N. pygmaeus* have made an evolutionarily significant shift away from an earlier, more arid-adapted condition. We consider that it is worth retaining *Nesotragus*, if only provisionally, because the Suni clearly retains a more conservative way of life and some key dental and cranial features associated with its less derived condition. Because this is a monospecific genus the species profile should be consulted for all descriptive details.

of $2n = 56$ (for the form *zuluensis*), but populations from Kenya (*akeleyi*) had $2n = 52$. They also recorded $2n = 53-55$ cytotypes, which they suggested were probably the result of hybridization in captivity between the two subspecies, and stated that it was possible that these cytotypes could occur in the wild.

Description A small, brown antelope with long, slender legs, a compact stance and a broad head and short neck. Preorbital face glands are disproportionately large, especially in adult ♂♂. The skin surrounding the eyes is almost bare but there is a short row of long vibrissae above the eye and others on the muzzle. Oval-shaped ears bear a brush of white hairs along their upper, inner margin. Inner surfaces of the ear are naked, pinkish and semi-transparent in strong light. The chin and upper throat are whitish, as is the lower chest. Body and neck are relatively uniform dark brown, the pelage being sleek and shiny with a very fine freckle. There are individual and possibly regional variations in tints of rufous or grey to body colour. The underside and inner surfaces of the legs are white or pale grey. Legs are tawny brown on their outer surfaces. The tips of the feet are black or dark brown ending in small, sharp, glossy black hooves; there are no lateral hooves. Deeply evaginated pedal glands are revealed when the toes of the hindfeet are splayed. The area of longer black hairs around and under the hoof coincides with the zone of scent diffusion from the pedal glands. Tail short, well haired and black on its outer surface, vivid white below: it is frequently wagged from side to side. Inguinal glands are present. Females have two pairs of inguinal nipples.

Males have strongly ridged horns that reach a maximum length of around 130 mm, and are heavily annulated with up to 20 well-marked annuli. Females are hornless. The skull is distinctive in that there is a vacuity or fontanelle between the maxilla and premaxilla. This suggests that the latter bone might have made an evolutionary migration upwards from a shorter, lower attachment to the maxilla (Kingdon 1982). Likewise, the nasal bones appear to be secondarily elongated forwards and downwards. The maxilla and lachrymal bones appear to have accommodated massive enlargement of the preorbital glands by becoming deeply convex, thus narrowing the

Lateral and palatal views of skull of Suni *Nesotragus moschatus*.

nasal chamber. This, together with the downwardly bent nasals, give the diminutive snout of the Suni a distinctly 'pinched' appearance. Kingdon (1982) interpreted these peculiarities in terms of a phyletic shift into more humid environments and abandonment of a 'nasal bellows' mechanism in a drought-adapted ancestor. A small ethmoid fissure is present (as in the Royal Antelope *Neotragus pygmaeus*). The teeth, particularly the premolars, are proportionally exceptionally robust for such a small antelope. Upper milk canines are absent.

Geographic Variation Five subspecies have been recognized: *N. m. moschatus* (including *zanzibarcus*), from the Zanzibar Is.; *N. m. akeleyi*, from Mt Kenya, the Aberdares and south to Nairobi; *N. m. kirchenpaueri*, from coastal S Kenya, NE Tanzania and Mafia I.; *N. m. livingstonianus*, from S Tanzania, Malawi and N Mozambique; and *N. m. zuluensis*, from NE South Africa, S Mozambique and Zimbabwe (Haltenorth 1963, Ansell 1972). However, the limits between them are equivocal and the descriptions are based on limited specimens. Consequently, most authors have regarded the validity of these forms as doubtful. Nevertheless, geographical variation is evident in some areas. In East Africa, authors have distinguished between a dark highland form (considered by some as the subspecies *N. m. kirchenpaueri*) and a paler, coastal form (*N. m. moschatus*). Grubb (1989) examined skins of Sunis collected from Malawi and found that the Malawi population exhibits a range of variation comparable to that of Sunis in East Africa (but with more intergradation between extremes and in a smaller area) and allied these to the East African forms. In examining specimens from Mozambique, Grubb (1989) noted that these appear quite different from those in Malawi, being unspeckled and overall bright rufous brown with little contrast between the upperparts and shanks. These Sunis also were larger than East African animals, which Grubb (1989) noted implies an association with the form from KwaZulu–Natal in South Africa (*N. m. zuluensis*). However, because the Malawi and Mozambique specimens were

Upper-right tooththrow of Suni *Nesotragus moschatus*.

Nesotragus moschatus

taken from relatively close localities, Grubb (1989) suggested that the Zambezi R. marks a narrow zone in the geographical variation of this species, and recognized two divisions: the nominate *moschatus* division (including *kirchenpaueri* and *akeleyi*) and the *livingstonianus* division (including *zuluensis*).

Similar Species

Philantomba monticola. Sympatric in Tanzania, Kenya, S Malawi and Mozambique. Larger, greyer, with shorter legs, less conspicuous ears; tail mostly flipped up and down, not from side to side.

Neotragus batesi. Allopatric species from central and West Africa; smaller, more russet.

Neotragus pygmaeus. Allopatric species from West African Guinea forests; very small with russet rump.

Distribution Endemic to evergreen and semi-deciduous forests and thickets of eastern Africa from Kenya to KwaZulu–Natal, South Africa, mostly east of the Eastern Rift Valley. In Kenya, it occurs about as far north as Mt Kenya and the Aberdares, and, along the coast, has been recorded as far north as the Boni-Dodori forests (Andanje *et al.* 2011b). The species ranges southwards through the eastern half of Tanzania, including Mt Meru, Mbulu, the Ngorongoro Crater highlands and the Eastern Arc Mountain forests (such as North and South Pare, East Usambara, Nguu Mts and Udzungwa Mts; Cordeiro *et al.* 2005, Rovero *et al.* 2005), the lower Shire valley in S Malawi, NE and SE Zimbabwe, parts of Mozambique, and E South Africa. Their southerly limit of distribution is around L. St Lucia in NE KwaZulu–Natal (ca. 28°S). They probably also occur in extreme E Swaziland, although their occurrence is not confirmed (Monadjem 1998). There are no confirmed records from Zambia, although there are records south of the Zambezi around Kariba. Recorded from Zanzibar and some adjacent islands (Mafia and Chapani, the type locality), but not Pemba; introduced to Rubondo I. in L. Victoria in the 1960s (Rodgers *et al.* 1977).

Suni distribution was probably always discontinuous and fragmented but agricultural expansion into forests and thickets has accentuated this tendency. Whereas the area inhabited by Sunis has probably diminished considerably, the overall extent of their geographical range may not have contracted very much.

Habitat Thickets, forests and dense, evergreen woodlands from sea level to 2700 m. Commonest in forests fringing the foothills of larger mountains, in coastal forests on hills and in thickets and woodland on coastal coral-rag and sand dunes. Less common in montane forests dominated by cedar. Locally most abundant where there is thicker undergrowth along forest margins and water-courses. In some areas it probably benefits from the expansion of secondary thicket habitat that has resulted from human activity (e.g. on Zanzibar), and it readily colonizes degraded forests (East 1999).

Abundance In prime habitat (such as foothills of north Tanzanian mountains) relatively high population densities have been estimated. Ground surveys suggest densities of 13.0–17.0 ind/km² in areas like Zanzibar and Lengwe N. P., Malawi (East 1999). Sunis from fragmented, degraded and suboptimal habitats probably survive at lower densities. Densities of 0.9/km² are recorded from Mkhuzi G. R. in KwaZulu–Natal (Rowe-Rowe 1994). Based on these density estimates, East (1999) estimated a total population size of around 365,000 animals. Populations are probably stable over much of the range, but decreasing where hunting pressure is high. In addition, where they occur in protected areas with high densities of Nyala *Tragelaphus angasii*, and a corresponding decrease in the density of the shrub layer, their numbers decline.

Suni *Nesotragus moschatus* hindfoot splayed to expose pedal gland – note fan of hairs. Black fur coincides with area in which scent diffuses.

Adaptations The most striking peculiarity of the Suni is its strong, musky body scent and the inflated size of the preorbital face glands, especially in ♂♂. Although face glands may decline in size when animals are very old or sick, there seems to be no visible fluctuations in their size that can be correlated with sexual or seasonal cycles. Face glands on ♂♂ are used for frequent and intensive scent-marking of exceptionally small and compact territories. The tips of twigs and stems are inserted into the deep, central pocket of the gland, emerging with a blob of scented black secretion. Stems are mostly the product of browsing by folivores, but Sunis sometimes bite off leaves or buds before marking the cut stem tip. Somers *et al.* (1990) studied marking behaviour in captive Sunis and found that short, vertical twigs between 15 and 280 mm in height are favoured as marking posts. The secretion dries to a hard, dark, crystalline substance that, due to repeated markings, forms visible bulbous deposits. Such marks last about four days. Stander *et al.* (2002) employed gas chromatographic and gas chromatographic–mass spectrometric techniques to identify 83 compounds in the preorbital secretion of the male Suni. Facial scent-marks are mainly concentrated along regularly used trails that form a network throughout the territory. Trails are also likely to be well scented by interdigital pedal glands on the back feet (the other main source of scent production). Communal dung piles around the boundaries of territories provide further evidence for the supreme importance of scent signals in Suni life history.

Scents clearly serve internal communication among Suni, but there could be other dimensions. Although Sunis are ‘hiders’ when born and mothers swallow their young’s excreta, young acquire a strong scent very soon after birth. Such seeming advertisement of the young implies that ‘olfactory’ predators entering Suni territories might be effectively ‘swamped’ with scent clues. The ability to generate pheromones sufficient to scent all the paths in its habitat would count for very little where the antelope’s environment is less constricted. The Suni’s ability to spread its scent around is therefore dependent on a small home-range that, in turn, is made possible by an eclectic choice of food plants. Another, possibly incidental, effect of the Suni’s scent is that it may deter some species of flying insects: Sunis have been observed without attendant flies while neighbouring antelopes of other species were severely pestered (J. Kingdon pers. obs.).

In their dense habitat, Sunis are cryptic animals. Both sexes display a very conspicuous and species-specific visual signal by wagging their black and white tails from side to side (unlike the Blue Duiker *Philantomba monticola*, which mainly flips its tail up and down). This wagging may also serve as a short-range dispersal mechanism of scent from the anal region. The white scrotum of the ♂♂ is also an obvious visual feature when viewed from behind.

Sunis are most active after rainstorms or spells of dense mist, especially between nightfall and 22:00h and after 04:00h, and rest during the heat of the day. These observations are borne out by camera-trapping work in the Udzungwa Mts where Sunis are primarily crepuscular and nocturnal (Rovero *et al.* 2005). They avoid exposing themselves outside dense cover during the day. They are largely independent of drinking water, obtaining their moisture requirements from their food.

Foraging and Food Sunis are browsers, as classified by a detailed review of dietary preferences in African bovids (Gagnon & Chew 2000) and studies using stable carbon isotopes (Cerling *et al.* 2003).

Suni *Nesotragus moschatus*.

Experiments conducted in captivity have shown that Sunis are highly selective feeders, with a distinct preference for dicotyledonous leaves (Hoppe *et al.* 1983, Lawson 1986, 1989, Maloiy & Clemens 1999). In the wild, Sunis browse from a wide variety of understorey plants that occur in the semi-deciduous and evergreen forests and thickets of eastern Africa. Leaves and shoots of the aptly named 'Suni Hemp' *Crotalaria* spp. are favoured, and other common food plants include species from the genera *Acacia*, *Acalypha*, *Achyranthes*, *Cissus*, *Clematis*, *Commelina*, *Grewia*, *Justicia*, *Leucas*, *Microglossa*, *Sapium*, *Strychnos* and *Toddalia*; *Fleurya* and *Ipomoea* are preferred when wilted and they pick up various dry leaves fallen from the canopy (Heinichen 1972, Kingdon 1982). Prins *et al.* (2006) recorded a total of 70 items eaten in a dietary study in Maputo Elephant Reserve in S Mozambique.

In West Kilimanjaro, Sunis gather under feeding colobus monkeys to pick up dropped leaves and shoots, notably those of a local dominant, *Nuxia congesta*. They have also been recorded eating the fallen fruits of the wild fig *Ficus* sp. in KwaZulu-Natal (Taylor 1978), and *Ficus sycomorus* was an important part of the diet in the early wet season in

a study in S Mozambique (Prins *et al.* 2006). They also eat charcoal and termitary mushrooms, and have been reported to scrape soil away to expose the roots of certain herbs (Heinichen 1972, Kingdon 1982). Although grasses, such as finger grass *Digitaria* spp., have been recorded in the diet, Sunis, like dik-diks, are not equipped to digest cellulose efficiently (Hoppe *et al.* 1983). Hoppe *et al.* (1983) examined the rumens of Sunis in East Africa and found that their contents consisted of 84% dicotyledonous leaves, 4% stems, 6% fruit and 6% monocotyledonous material. On the other hand, Prins *et al.* (2006) recorded between 14% and 27% monocotyledons in the diet of animals in S Mozambique. Captive studies have shown that daily forage consumption rates are in the order of 30.6 g/kg of body weight and fluid intake 106 ml/kg body weight (Maloiy & Clemens 1999).

Sunis prefer to eat in an alert posture, with the head raised, after wrenching parts off their stems: larger leaves and branches are sometimes shaken vigorously. Sunis have a high metabolic rate (Lawson 1986) and feed in short bursts interspersed with rests.

Social and Reproductive Behaviour Sunis occur solitarily or in pairs, and occasionally in groups. Pairs comprised 50% of all encounters in one study (M. Davies, in Kingdon 1982), while in KwaZulu–Natal 77% of sightings were of single adults and 12% of adult pairs (Lawson 1986). Sunis are territorial and defend territories of approximately 3 ha (Kingdon 1982); Lawson (1986) recorded territories of 0.5–1.0 for ♂♂ and 0.9–4 for ♀♀ in KwaZulu–Natal. Male territories have well-defined borders (with little overlap), while territories of ♀♀ often occur almost entirely within the territory of a ♂.

Territories normally appear to be exclusive to a pair or family group. Where more than one ♀ (up to four recorded) shares a territory, the single ♂ associates more closely with just one ♀. Both sexes contribute to dung deposits that tend to be on or close to boundaries. Deposits are visited, checked and augmented on a regular, often daily, basis. Both urine and dung pellets are added on each visit. The ♀ generally precedes the ♂ in urinating and then excreting pellets on established dung deposits; the ♂, when present, then follows, overlaying his contributions to the pile. Sunis approaching one another briefly touch noses and apparently sniff one another's face glands before parting. On meeting, a ♂ sometimes briefly licks the face of its preferred female partner. Mutual grooming is not commonly seen in free-ranging Sunis, but when it does occur takes the form of one individual grooming the head, neck and shoulders of another, which then reciprocates. Animals tend to lie up alone, although a ♂ may rest within sight of his ♀. There is no evidence for seasonal movements or changes in territorial boundaries.

Males actively defend their territories, and ♂♂ entering the territories of others are met with energetic grating of the horns on plants and chases in which the aggressor champs his jaws while trying to strike glancing blows or parry horn jabs. During such confrontations, contestants have been seen to use their long tongues to self-lick their facial glands. In captive groups that ranged free in a confined area of natural habitat, ♀♀ sometimes exhibited aggression towards others, lowering the head with ears drawn back as if ready to butt. In this position, black markings on the top of the ears simulate horns and such threat gestures commonly caused the threatened ♀ to retreat.

When disturbed, animals 'freeze' or else creep away with the head held low, walking carefully on the points of their hooves. Frights (which can be set off by such familiar stimuli as the choruses of colobus monkeys) precipitate a very fast, zig-zag rush, sometimes accompanied by a wheezing double screech, followed by a stop and total immobility. Normally, flight does not seem to take animals out of their known territory but two family groups confined in a one-hectare paddock in natural habitat accommodated to their confinement by maintaining two separate territories. A dense thicket in each of these territories offered all animals a choice of refuge during alarms or frights. However, each ♂ always escorted his favourite ♀ back to his territory after every scare.

When a ♀ comes into oestrus the ♂ follows her closely, at which time her normally limp tail is raised and wagged horizontally. During her postpartum oestrus the ♂ closely and continuously attends the ♀ for about 12 hours. Before mating, the ♂ commonly approaches the ♀ from the side, pressing his chest into her flank. He strokes or strikes her belly or ribcage with one foreleg until she stands still and permits him to mount her, very briefly, from the rear. A captive ♀

Suni *Nesotragus moschatus* male arresting female movement with 'laufschatz' or foreleg-lift.

gave birth lying down on her side and uttered some high-pitched bleats before the young came out. The placenta, which emerged 15 minutes later, was eaten immediately. The newborn young hides in thick vegetation and only emerges in response to the mother's soft bleat. The young makes a call that sounds like two marbles being ground together, so quiet that it is inaudible to the human ear at a distance of one metre; it may have ultrasonic components. The young finds the nipple with strong combing and champing movements and suckles strongly but very briefly. It can only suck through the very front of the narrow mouth. Any alarm sends the young in a fast, skulking run straight for cover with its ears back. As it gets older, the young emerges more frequently to seek or anticipate its mother. After suckling, she stimulates the young to excrete by licking the genital area and swallows its excreta. After weaning, juveniles begin to excrete on dung piles.

Sunis are not only alert to predators but seem to pay attention to the activity of monkeys, notably Angola Colobus *Colobus angolensis* and Guereza *C. guereza*. This attention often rewards the Sunis with a rich supply of fallen leaves and shoots.

Reproduction and Population Structure Breeding is known to occur in most months of the year. However, there is thought to be a birth peak between Nov and Feb in NE Tanzania (during the 'short rains' that follow the long dry season). This effectively ensures that both the mother and her offspring benefit from renewed growth. In captivity, Sunis exhibit no peak birth season (Spence 2003) and Lawson (1986) recorded mean age of ♀♀ at birth of the first young was 589 days and mean parturition interval 221 days; Pretorius *et al.* (1996) give mean age of ♀♀ at first birth as 472 days, and mean parturition interval as 209 days (which is similar to recorded birth intervals of 203 and 214 days for two captive ♀♀; Spence 2003). The oestrous cycle ranges from 20 to 25 days (Loskutoff *et al.* 1990). Gestation periods, recorded from two known instances of conception, were 172 and 192 days (Pretorius *et al.* 1996); Spence (2003) gives an estimated gestation period of 171–180 days based on captive animals.

Normally only one young is born at a time, with a birth weight of approximately 700–800 g. The lactation period is short and the young start nibbling at vegetation within a few days of birth (and

start ruminating at 30–32 days). Females mature at about a year; ♂♂ may be sexually potent before they are one year old but only acquire fully adult characteristics (full body size, enlarged face glands, sharp, annulated horns and a particularly sleek pelage) at about 14 months. The territorial ♂ expels young ♂♂ when they show the first sign of horns (about 6–8 months). Lawson (1986) reported that in captivity ♂♂ eight months of age had to be separated from adult ♂♂ because they started to fight. Young ♂♂ placed in separate enclosures showed no signs of overt fighting, although a definite dominance hierarchy was evident. However, the introduction of a young ♀ to the enclosure caused fighting.

In captivity or confinement, ♀♀ commonly remain with the parents after maturity and it is possible that some 'harem-like' wild groups include the female offspring of resident pairs. While some 50% of recorded encounters in one N Tanzanian study were of pairs, a surplus of ♀♀ in some localities was reflected in other single-male groups with 2–4 ♀♀. A higher ratio of ♀♀ in some populations is probably due to male deaths following fierce territorial contests. Male/female ratios appear to vary locally but were estimated to be in the region of 1 : 2.5 in the foothills of Mt Kilimanjaro (M. Davis pers. comm.). Captive animals have been recorded living to more than 13 years (Jones 1993, Weigl 2005).

Predators, Parasites and Diseases Suni remains are commonly found below the nests of Crowned Eagles *Stephanoaetus coronatus* (e.g. Brown 1966). Other species of large eagle, such as the Martial Eagle *Polemaetus bellicosus*, are also likely to take them. Other likely, but probably less frequent, predators include African Rock Pythons *Python sebae*, Side-striped Jackals *Canis adustus* and Leopards *Panthera pardus*. Sillero-Zubiri & Gottelli (1992) reported them being preyed on in the Aberdares Mts by Spotted Hyenas *Crocuta crocuta*.

Khalil & Gibbons (1976) recovered ten helminth species from Sunis in Kenya, two of which were new species of nematodes, *Trichostrongylus moschatus* and *Megacooperia woodfordi*. Boomker *et al.* (1991a) recorded nine nematode species from KwaZulu–Natal, South Africa, including two *Cooperia* spp., *Haemonchus vegliai*, *Setaria cornuta*, *Strongyloides papillosus* and two *Trichostrongylus* spp. Eight of these were new parasite records for the Suni in Africa, with the exception of *M. woodfordi* (probably a host-specific parasite). Golezardy & Horak (2006) recorded the ticks *Haemaphysalis parvata* and *Rhipicephalus kochi* from three animals in South Africa.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although very localized in an environment that is subject to much depletion (for wood, charcoal and farmland), Sunis remain widespread through much of their range, presumably aided by their ability to adapt to secondary degraded vegetation. However, domestic dogs do pose a problem for this species. For example, Sunis were common in the natural thickets of the Langata suburban properties of Nairobi in 1968. At that time few properties were fenced. However, in the next decade or so many were fenced with chain-link or wire netting through which Sunis could not pass. As soon as this happened, the Sunis were quickly eliminated by domestic dogs that they had hitherto managed to evade (I. Parker pers. comm.). Several studies that have reported on hunting of Sunis confirm the widespread use of dogs (e.g. Carpaneto & Fusari 2000, Cordeiro *et al.* 2005).

Sunis are well represented in the conservation areas of several eastern African countries, notably: Mt Kenya N. P., Aberdare N. P., Shimba N. P., Sokoke/Arabuko F. R. (Kenya), Udzungwa Mountains N. P. and other forest reserves in the Udzungwas, Ulugurus, Usambaras and Southern Highlands, Selous G. R., Lake Manyara N. P. and Jozani F. R. (Zanzibar) in Tanzania; Lengwe N. P. (Malawi); Gorongosa N. P. and Maputo G. R. (Mozambique); and Tembe N. P., Mkhuzi G. R. and Ndumo G. R. (KwaZulu–Natal, South Africa).

Tribe CEPHALOPHINI

Duikers

Cephalophini Blyth, 1863*. Cat. Mamm. Mus. Asiat. Soc., p. 167.

*Attribution of Blyth as the author, and not Gray, 1871, follows Grubb (2001a).

Weyns's Duiker *Cephalophus weynsi* skeleton.

The tribe Cephalophini includes the duikers, and, at least in the current work, comprises three genera and 19 species (see Grubb & Groves 2001 and Grubb 2005 for alternative recent classifications). Duikers are, and always have been, uniquely African forest antelopes. They have compact bodies and are small- to medium-sized animals, ranging in size from 3.5 to 80 kg in Jentink's Duiker *Cephalophus jentinki*. Both sexes (though not, normally, *Sylvicapra*) usually have short, simple horns and short wedge-shaped heads. The mouth is large, with a wide maw, which can, in most species, be correlated with eating fruit. Less obvious is their possession of brains that are larger and more complex than in any other bovid (Oboussier 1966, 1979). This is a clear indication that duikers are not simply a primitive group, and large brains also hint at the dependence of duikers on tracking events in the forest canopy, where most of their food derives from the wasteful foraging of arboreal animals, from wind and from gravity. The skull is characterized by massive enlargement and thickening of the frontal bones, which have expanded front and back with concomitant rooting of the horns in a more posterior

Weyns's Duiker *Cephalophus weynsi* forehead and horn sectioned to show exceptional thickening of frontal bone (from Kingdon 1982).

position. In some species there has been such heavy ossification of the frontals that it clearly serves as a shield and battering ram, a feature unique to duikers. Kingdon (1982) ascribed this frontal shield (and other peculiarities) to extensive remodelling following dwarfing in a remote ancestor.

All species have preorbital glands on the sides of their muzzle (with concomitant preorbital fossae), each of which has eight or more secreting pores that are aligned in roughly horizontal rows across the surface of the glands. These are unlike the single invaginated pockets of many other antelope groups (which are adapted to place long-lasting gobs of secretion on twigs or stems). In relation to the evolution of multiple pore-like preorbital glands it may be significant that the smallest of living *Neotragus* species, the Royal Antelope *N. pygmaeus*, has greatly reduced, but still mono-orificed, preorbital glands. This implies that if the earliest proto-duikers had minuscule glands there might have been more potential for restructuring of a semi-vestigial gland, which could help explain such a marked difference from most other Antilopinae. The small, multiple pores are 'smeared' on vertical stems, tree trunks or on other duikers. Some species have inguinal glands, under tufts of hair on the legs or between the hooves. General body proportions vary from species to species, but all follow a 'run and hide' strategy to escape predators and the length of their legs bears no comparison with open-country antelopes that escape danger by running. Females often larger than ♂♂. Females have two pairs of inguinal nipples. Further details specific to individual species are provided below in the individual species profiles. Wilson (2001) has provided a detailed overview of the duikers, of a sort well beyond the scope of the current work.

The affinities and supposed origins of duikers have generated more diverse suggestions than perhaps any other group of antelopes. They were once thought to be among the most primitive of bovids, mainly because they are relatively omnivorous and had 'remained' in the forest habitats that were once assumed to be the ancestral home of bovids. These assumptions pictured duikers forming some sort of phylogenetic bridge between chevrotains and bovids (Estes 1974). Making bovid-wide comparisons between different morphologies, scientists studying bovids have put forward their closest affinities as follows: (1) sister-group of the Bovinae (Gentry 1992); (2) in an intermediate position between Bovinae and Antilopinae (Jansen van Vuuren & Robinson 2001); (3) clustered with the non-Bovinae (Georgiadis *et al.* 1990, authors who did not specifically associate them with any other tribe);

Black-fronted Duiker *Cephalophus nigrifrons* facial features.

Aders's Duiker *Cephalophus adersi* myology.

(4) allied with the Reduncini (Gatesy & Arctander 2000a, Kuznetsova *et al.* 2002), a suggestion that was reiterated by Hernández Fernández & Vrba (2005); (5) with a clade containing reduncines, hippotragines and alcelaphines (Gatesy & Arctander 2000b); and (6) as sister taxon to the Klipspringer *Oreotragus oreotragus* (Hassanin & Douzery 1999, Matthee & Robinson 1999a, Hassanin *et al.* 2012), although evidence to the contrary was presented by Matthee & Davis (2001). The diversity of these suggestions derives from the mosaic of similarities and dissimilarities that seem as evident in the genes of duikers as in their gross morphology.

A different approach has been to turn to what duikers do that is different from other bovids and place those differences in the biogeographic and ecological contexts that might have led to this uniquely African radiation of at least 19 forest antelope species. Such an approach can then be compared with molecular data, particularly for clues as to which species and characteristics might be primitive and which specialized. For a start, where do duikers stand if they are, as genetic research suggests, not a basal, primitive group? Those antelopes retaining a predominance of primitive states are mostly small and their initial adaptation, on entering Africa, was not to moist forests, but to dry thickets; most significant of all, primitive Antilopinae were/are unambiguously folivorous. There is nothing in their biology to suggest that duikers could have evolved in such habitats and frugivory, their principal characteristic, could only have evolved within the equatorial forests of Africa, where most of them still live today. What kind of incremental progression could convert a dry, low, thicket-dwelling folivore in north-eastern or eastern Africa into moist, high-forest frugivores living mostly along the equatorial axis?

Ignoring any possibility of early changes in the fundamentals of antilopine diet, it becomes much more likely that the earliest lineage of antelopes to adapt to the forests of equatorial Africa remained folivorous. Such antelopes exist today, in the form of three species of dwarf antelope (*Neotragus* and *Nesotragus*), which do, indeed, retain primitive conditions, but it is important to remember that contemporary species can only hint at what happened amongst their ancestors some 17–15 mya. It is more likely than not that duikers share a very ancient ancestry with today's dwarf antelope species (or, according to some authors, from some unknown, extinct offshoot from the Oreotragini). It seems at first peculiarly counter-intuitive to accept that advanced ruminant folivorous diets could be 'primitive' whereas highly nutritive and easily digested fruit and seed diets are

'advanced' when it comes to duikers, yet this dietary staple in itself implies a specialist niche, dependent for its very existence on the presence of a diverse guild of arboreal forest frugivores.

Biogeographic and ecological interpretations of the beginnings of duiker evolution invoke multiple lines of evidence and can be measured against certain environmental constraints on what is or is not possible. What were the primary characteristics of a proto-duiker? At least three groups of antelopes show a rough progression from smaller conservative types to larger derived ones; a natural outcome since most ancestral Antilopinae were relatively small. Among duikers, the very small species are the most conservative (at least two species buffer shortages of fruit with leaves), while all the largest are the most derived and the most recently evolved (and for the most part, strongly frugivorous). Intermediate forms follow an almost linear progression from smaller to larger, and dwarfing is one mechanism whereby a leaf-eating herbivore can survive in high forest

Phylogenetic tree for Cephalophini (adapted from Jansen van Vuuren & Robinson 2001 and Hassanin *et al.* 2012).

where ground-level herbage is scarce. A dwarf ancestor for duikers is therefore wholly consistent with the facts.

The suggestion that duikers originate from diminutive ancestors has found some corroboration in molecular trees that show that the larger species are among the most recently evolved while the smallest are the more ancient, in the sense of being more deeply divergent (Jansen van Vuuren & Robinson 2001). The duikers are therefore likely to be a secondary radiation diverging from early Neotragini or Oreotragini. As for timing, Hernández Fernández & Vrba (2005) suggest duikers emerging at about 14 mya (similar to Hassanin *et al.* 2012), although the earliest fossils are only about 3 mya (Makapansgat, South Africa; Gentry 1978). Extended arguments for the duikers' origins were detailed in Kingdon (1982), and summarized in Kingdon (1997).

Most duikers live only in forest but some have adapted to more open, swampy or montane environments. Duikers are rare in the fossil record and there are no fossils to suggest that they ever crossed the Sahara, let alone left Africa. The species profiles that follow detail some very interesting forms of ecological partitioning among duikers. The proliferation of at least 19 living species (and probably more) involves both isolation, regional specialization and partitioning of the habitat by food type and seed-size, activity (diurnal and nocturnal, localized, dispersed) and, above all, size differences. All duikers are dependent, to a greater or lesser degree, on primates, birds and fruit-bats to dislodge the fruits, flowers and leaves on which they feed. Part of their alertness and 'strategic intelligence' is linked with this sensitivity to what is happening in the canopy.

Some duikers can clamber up sloping trunks or dense tangles. One group have specialized in skilled concealment (mostly during the day), relying on a short, fast dash to escape if found. These, the fibre duikers, the Bay Duiker *C. dorsalis* and Jentink's Duiker *C. jentinki*, have a different body build from other duikers (notably in their powerfully muscled hindquarters). Explosive leaping is less typical of species with more continuous exposure, but all can make prodigious leaps when pursued.

All species are thought to be territorial and most form close associations between the sexes, each excluding others of their own sex. The size of territories and degree of exclusivity, particularly along margins, probably varies a great deal. Well-trodden paths connect habitual feeding, ruminating, sleeping and refuge areas. All species use scents and vocalizations to regulate social contacts. Precocious young are born after a relatively long gestation. All are slow to reach full maturity, suggesting that prolonged learning may be necessary for successful exploitation of a difficult environment.

The thickened and enlarged frontal bones of duikers and their short, sometimes vestigial horns grow from further back on the skull than in other antelopes. This can be correlated with hard head-butting in some species, directed at rivals and (less commonly) predators and hard

fruits. Their reduced horns and other neotenuous features are further indications of dwarfed origins.

As an actively speciating group, some duiker species could be predicted to be actively expanding their range while others might be in competitive decline or subject to 'hybridization' with close relatives. The evidence for such processes taking place is detailed in some species profiles. However, all such possibilities are overshadowed by the massive and totally unregulated onslaught of the highly profitable bushmeat trade on all species. Duikers are easy to snare, net, call up to a lure, dazzle by flash-light and hunt with dogs. The rarer, large-bodied species are already close to extinction and many others are known to be in decline. As one of the most interesting and complex of bovid evolutionary radiations, they deserve much more attention than they have to date. The most likely of all predictions about duikers is the imminent extinction of many of the rarer species. With that extinction science and culture will be deprived of a vast store of information about the evolution of African forests and their inhabitants.

Jonathan Kingdon & Colin Groves

Blue Duiker *Philantomba monticola* myology.

GENUS *Philantomba*

Blue Duikers

Philantomba Blyth, 1840. In: Cuvier's Anim. Kingd., p. 140.

Traditionally, this genus has been regarded as a synonym or, at most, a subgenus of *Cephalophus*. However, Grubb & Groves (2001) regarded it as a valid genus and their cladistic analysis placed it as sister not to *Cephalophus*, but to *Sylvicapra*. Independently, Jansen van Vuuren & Robinson (2001), using two mtDNA sequences, found that *Philantomba* is sister to *Sylvicapra* + *Cephalophus*, with good bootstrap support.

Philantomba are diminutive duikers, the head and body being less than 75 cm in length. Characteristic is the thick mat of hair on the forehead, which is darker and more brown than the face itself. There is usually (but not always) a red or buff-coloured stripe above each eye. The pelage does not change with age; the hairs are uniformly coloured, usually some shade of brown, darker on the dorsum on the flanks, and there

is commonly a sharp transition between the dark and light tones on the haunch. As in *Sylvicapra*, the tail is even-haired, not tufted. The skull is small and delicate, relatively broad across the braincase and frontal region, and suddenly constricted on the rostrum, so that the anterior width of the nasals is only half that at the frontonasal suture. The occipital plane and paraoccipital processes are oblique; the orbits are somewhat tubular, and their dorsal rims protrude somewhat above the plane of the frontals (all these features are as in *Sylvicapra*). The preorbital fossa is very extensive, but shallow. The horns are very small and delicate, and upturned at the tips; in ♀♀ they are much reduced and often absent. In the pelvis the lengths of the ilium and ischium are approximately equal, as in *Sylvicapra*. Apart from these diagnostic features, other characters (sometimes also found in members of the genus *Cephalophus*) include the fully haired, untufted tail, the lack of inguinal glands, the absence of a true crest and the tendency to show reversal of the neck hair (Grubb & Groves 2001).

The genus includes two species with allopatric distribution: Maxwell's Duiker *Philantomba maxwelli*, which occurs west of the

Cross R.; and Blue Duiker *P. monticola*, which ranges from east of the Cross R. to southern Africa. Note that as *Mammals of Africa* was being finalized, a species-level revision of the genus in West Africa, involving both morphology and genetic data, revealed the existence of a third species, Walter's Duiker *Philantomba walteri*, occurring in the Dahomey Gap (Togo, Benin) and the Niger Delta (Colyn *et al.* 2010). Although we have not been able to include a species profile, Walter's Duiker is intermediate in size between the larger *P. maxwelli* to the west and the smaller *P. monticola* to the east. Externally, the new species resembles *P. maxwelli* because of its relatively long tail (>15 cm), large pedal gland, a striking superciliary line, the absence of a strongly marked break on the haunches between the dark croup, light colored flanks and lower haunches. Craniometrically, *P. walteri* can be differentiated from the two other species in the genus by a clearly smaller nasal constriction and cranial height (Colyn *et al.* 2010).

Colin Groves

Philantomba maxwelli MAXWELL'S DUICKER

Fr. Céphalophe de Maxwell; Ger. Maxwellducker

Philantomba maxwellii (C. H. Smith, 1827). In: Griffith *et al.*, Anim. Kingd. 4: 267. Sierra Leone.

Maxwell's Duiker *Philantomba maxwelli*.

Lateral view of skull of Maxwell's Duiker *Philantomba maxwelli*.

The species is named for Sir Charles William Maxwell, who was Governor of Senegal in 1809 and then of Sierra Leone (origin of the type) in 1811.

Taxonomy Ansell (1972) and Ralls (1973) recognized three subspecies: the nominate form from Senegal and Gambia to Sierra Leone; *P. m. lowei* (including the form *danei*) from the islands in the Rokelle R. in Sierra Leone and with unknown limits; and *P. m. liberiensis*, from Liberia eastwards. Grubb & Groves (2001) recognize two subspecies: the nominate form, *P. m. maxwelli*, is distributed through the species range except for the Yatward and Sherbro Is., where it is replaced by the subspecies *P. m. danei*, which is smaller (skull length under 136 mm). Synonyms: *danei*, *frederici*, *liberiensis*, *lowei*, *philantomba*, *whitfieldi*. Chromosome number: $2n = 60$; Maxwell's Duiker has only acrocentric X chromosomes (Hard 1969, Robinson *et al.* 1996b).

Description Small-sized antelope varying in colour from light, sandy-brown to greyish-brown or brownish-black. The narrow and angular face tapers off to a small pointed muzzle. The upper jaw clearly surpasses the lower jaw and the mouth droops, which gives the Maxwell's Duiker a grim facial expression. There is no definite crest between the horns. The curved preorbital glands are heavily demarcated, and studded with as many as 25 pores. There is frequently a lighter brow-like line above the large black eyes. The oval ears are frequently fringed with white, and together with the tail, which is white below, are constantly flicked back and forth, making conspicuous fieldmarks. The belly and inside of legs are paler than the rest of the body. The slightly elongated rump and relatively narrow neck give a lighter build to this animal than to other duikers. The legs are very slim and relatively long, and the buttocks are angular. The tail is fully haired and untufted (Grubb & Groves 2001). There are no inguinal glands, and the well-developed pedal glands lie in a subcircular sac at the end of a narrow canal (Pocock 1910). Horns are short (seldom more than 6 cm), heavily ridged, thick at the base, and bent slightly inwards and backwards. Horns are frequently lacking in ♀♀, and when present are usually much shorter and less heavy at the base (Wilson 2001).

Geographic Variation

P. m. maxwelli: distribution as for species, but not present on Yatward and Sherbro Is. There is some evidence of geographical variation in anatomical features, but patterns of variation are complex (Grubb & Groves 2001). The frequency of nuchal hair reversal increases from west to east. Most measurements of skull size increase from east to west between Togo and Liberia, but there are discrepancies from this pattern in Ghana, and the pattern does not hold for the extreme eastern and western parts of the range. The length of horns in ♂♂ decreases from east to west, but again, Ghana does not entirely fit the pattern, and horns are largest in the extreme west. The proportion of ♀♀ with horns decreases westwards from 100% in Nigeria and Togo to only 5 out of 80 in Liberia, but there are few data for the west of the range. Geographical variation in coat colour is masked by a high degree of individual variation (Grubb & Groves 2001).

P. m. danei: Yatward and Sherbro Is. Small size: skull length 128–136 mm (cf. >136 mm in *P. m. maxwelli*); nasals 40–44 mm (cf. >45 mm in *P. m. maxwelli*); preorbital 64–65 mm (cf. >66 mm in *P. m. maxwelli*); and toothrow 36–41 mm (cf. >41 mm in *P. m. maxwelli*).

Similar Species

Philantomba monticola. The two species are separated geographically, with Maxwell's Duiker occurring to the west of the Cross R., and the Blue Duiker to the east. Blue Duikers are significantly smaller; according to Grubb & Groves (2001), the largest skull of a Blue Duiker they recorded was 139 mm, whereas this is closer to the minimum for Maxwell's Duiker; also differs in colour (with strongly marked break on the haunches between the dark croup and the light colour of the flanks and lower haunches; cheeks are darker and superciliary streaks less prominent); length of tail (usually less than 100 mm); a shallower, smaller pedal gland; and cranial characteristics (skull narrower across the zygomata; orbital borders more protuberant; rostrum more

constricted; narrower palate; free ends of nasals narrower on average) (Grubb & Groves 2001).

Distribution Endemic to Africa. Widespread within the Upper Guinean forest zone, in lowland forests and extending into forest–savanna mosaics, from W Gambia and SW Senegal east to the Cross R. in Nigeria (East 1999, Wilson 2001). Distribution is restricted by the drier savanna–sahel zone in the north. Since they do occur in gallery forests within savanna woodlands in parts of West Africa (e.g. N Côte d'Ivoire and SW Burkina Faso), it is reasonable to assume that they may occur in SW Mali, though there are no confirmed records to date (Wilson 2001). Their current distribution is probably not much changed from their historical distribution, although much of their original habitat has been modified or lost.

Habitat Found in mature and secondary forests, gallery forests and forest patches, coastal scrub and farmland (Aeschlimann 1963, Davies 1987, Newing 1994, 2001, Grubb *et al.* 1998). They have a preference for dense undergrowth, but occasionally penetrate into fields close to forest patches. They adapt well to farmland and in Sierra Leone they occur on montane grassland over 1400 m on the Loma Mts. The animals do not require permanent water within their territories, even if nursing, provided enough fresh fruits are available (Nett 1999).

Abundance Abundant throughout the forest zone in both mature forests and secondary vegetation, but decreasing where hunting pressure is high. Davies (1991) estimated population densities of 15–30/km² in mature logged forest in Gola N. P., Sierra Leone, and Wilson (2001) thought this was the most common antelope in the country. This is also the most common duiker in Côte d'Ivoire, where Newing (1994, 2001) recorded a density of 79/km² in a mixed, hunted farmland near Tai N. P. and 63/km² in lightly logged primary forest with minimal hunting, within the Park. Elsewhere in Côte d'Ivoire, Nett (1999) recorded 16–20/km² in heavily hunted and logged semi-deciduous forest patches in the eastern part of the country, and Hoppe-Dominik (1989) found 2.7/km² in the savanna–forest mosaics of Marahoué N. P. In the National Park of Upper Niger, Guinea, Maxwell's Duikers had the highest density (3.7/km²) of a total of ten species of ungulates present (Brugière *et al.* 2005). East (1999) suggested a total population size of 2,137,000 individuals – likely a conservative estimate.

Adaptations Maxwell's Duiker is the smallest and most opportunistic of seven sympatric duiker species in the Upper Guinean forest block. It inhabits even heavily degraded forest patches and hides in the dense cover of the exotic Akyempong weed species *Chromolaena odorata* (Newing 1994, 2001, Nett 1999). Wilson (2001) suggests that numbers may even have increased as a result of forest clearance for farmland and the spread of Akyempong. The success of Maxwell's Duikers in secondary vegetation types is doubtless made possible by a very broad diet including a large variety of small fruits and leaves, and an ability to adapt to a more leafy diet at times of fruit scarcity (Newing 1994). In contrast, the sympatric species are significantly larger than Maxwell's Duiker (Bay Duiker *Cephalophus dorsalis*, Black Duiker *Cephalophus niger*, Yellow-Backed Duiker *Cephalophus silvicultor* and Jentink's Duiker *Cephalophus jentinki*) and/or more restricted to mature forest (Zebra Duiker *Cephalophus zebra*,

Philantomba maxwelli

Jentink's Duiker and Ogilby's Duiker *Cephalophus ogilbyi*) or to secondary forest (Yellow-backed Duiker) (Newing 2001).

Foraging and Food Maxwell's Duikers are primarily frugivorous, but also eat leaves and mushrooms and may depend on leaves at times of fruit shortage. The two most comprehensive studies of feeding ecology to date are those of Hofmann & Roth (2003) and Wilson (2001). Hofmann & Roth (2003) examined 139 stomachs from the bushmeat market of Toumodi in Côte d'Ivoire. These authors recorded 78 different types of fruits eaten, with Maxwell's Duikers showing a particular preference for *Nauclea latifolia*, *Ficus capensis*, *Canthium vulgare*, *Blighia sapida*, *Griffonia simplicifolia*, *Alchornea cordifolia*, *Phoenix reclinata* and *Spondias mombin*. Wilson (2001) examined 250 stomachs from bushmeat markets in Ghana, and listed 33 species of fruit, including *Ficus* spp., *Solanum* spp., *Blighia* spp. and *Uvaria* spp.; all fruits eaten were from cultivated lands, secondary forest or savanna. Both Wilson (2001) and Hofmann & Roth (2003) recorded an average of three fruits per stomach. In the eastern semi-deciduous forests of Côte d'Ivoire, hunters named the fruits of *Ricinodendron heudelotii*, *Strombosia glaucescens*, *Trichilia monadelpha* (= *T. heudelotii*), *Ficus exasperata*, *Celtis adolfi-fridericii* and *Ceiba pentandra* as their primary food sources (D. Nett pers. obs.). Aeschlimann (1963) examined two stomachs of Maxwell's Duikers in the evergreen forest zone and found seeds of *Turraeanthus africanus* and *Pycnanthus angolensis*; fruits of *Musanga cecropioides*; leaves of *Griffonia simplicifolia*, *Ficus barteri*, *Baphia nitida* and *Fagara parvifolia*, and several varieties of mushrooms. Newing (1994, 2001) listed 26 species of fruits found in eight stomach samples and a further two species eaten during direct observations of free-living animals in mature forest. Hofmann & Roth (2003) and Wilson (2001) both recorded animal matter in the form of ants from stomachs.

In suitable habitats Maxwell's Duikers are said to follow groups of colobus monkeys and guenons, in order to profit from fallen fruits. The guenons include the Lesser Spot-nosed Guenon *Cercopithecus (cephus) petaurista*, Mona Monkeys *Cercopithecus mona* and Diana Monkeys *Cercopithecus diana*. In heavily degraded forests Maxwell's Duikers are often found in close association with squirrels, which may take over the primates' ecological role when the latter are no longer abundant (Nett 1999). Maxwell's Duikers have a bimodal diurnal activity pattern with peaks in the early morning and late afternoon.

Social and Reproductive Behaviour Maxwell's Duikers live in monogamous pairs or occasionally polygamous groups (e.g. Tai N. P.; Newing 1994) with or without young, with a common territory. Newing (1994) recorded home-range sizes of about 5 ha in mature forest and 3.6 ha in secondary vegetation, while Nett (1999) recorded 18.4 ha in relict forest. Territory size seems to increase with the age of the animal (e.g. 12.5 ha for one subadult compared with an average of 20 ha each for three adult animals). Territory size also appears to decrease in accordance with increasing available resources (especially fruits) and shows no seasonal changes. Overlap between territories of neighbouring groups is small (0–23%) and temporary. In a shared territory the borders of the female's territory sometimes lie outside the male's, suggesting that both sexes mark and defend against conspecifics (Nett 1999). Newing (1994) observed physical fights between neighbouring ♂♂ and chases of ♂♂ or male–female couples by neighbouring ♂♂. Ralls (1975) observed Maxwell's Duikers in captivity and documented agonistic behaviour in both

sexes, even though fighting was much more aggressive in ♂♂. The author described Maxwell's Duikers as extremely pugnacious with the ability to chase even other antelopes such as the larger Bay Duiker. Territorial boundaries are marked by middens and scent-marking. Mutual scent-marking with the preorbital glands strengthens the bonds of a monogamous pair; it is also carried out by two individuals of the same sex prior to heavy fighting. All marking is carried out by both sexes.

Courtship is initiated by the ♂, who pursues the ♀ and attempts to lick the base of her tail while the ♀ may be lifted off her hindfeet. Ralls (1973) reports that the tail of an oestrous ♀ is often wet and frayed from the male's intensive chewing and biting. Circling nose-to-tail, flehmen (lip curling) and laufschiag (leg tapping) precede mounting attempts; the ♀ only stands still once she is ready to mate, and copulation is very brief. Maternal care is reduced to a minimum in Maxwell's Duikers even though the mother grooms the young by licking its fur. The young does not follow its mother but is laid up in a protected spot until about three months old, when it begins eating significant amounts of fruits and leaves (Wilson 2001, H. Newing pers. obs.).

Two kinds of nasal vocalization accompany fighting, sexual and anti-predator displays: an often repeated short snorting and the louder intense alarm-call. The latter seems to have disappeared in some areas where hunting pressure is heavy, since hunters try to attract the animals by imitating these calls, and even playbacks no longer elicit a response. This might be an adaptation of Maxwell's Duikers to human pressure (Nett 1999).

Reproduction and Population Structure Births occur throughout the year. In Côte d'Ivoire and Nigeria there is a suggestion of two birth peaks – one in the main dry seasons, from Dec to Mar, and one from Jul to Sep (Aeschlimann 1963, Happold 1987, Newing 1994), but Wilson (2001) could not find any evidence of a birth peak in Ghana. Of 131 uteri examined by Wilson (2001), every one had the foetus implanted in the right uterine horn, although ovulation took place from either ovary. A single young is born that resembles the parents in colour, and weighs between 600 and 950 g (Aeschlimann 1963, Wilson 2001).

Basic information on length of gestation period and age at sexual maturity remains contradictory. Numerous authors have cited a gestation period of 120 days (e.g. Aeschlimann 1963, Ralls 1973); however, Kadjo (2000) gave gestation as 188 days and Wilson (2001) gives a mean gestation length of 205 days ($n = 4$; range 198–213). Hofmann *et al.* (1998) recorded first oestrus in ♀♀ of a heavily hunted wild population at six months. Wilson (2001) recorded four captive ♀♀ conceiving at between 8 and 12 months, and earliest successful mating by a ♂ at 10 months. However, Kadjo (2000) recorded first oestrus only at 18 months. Females become receptive 3–5 days after giving birth.

Hofmann *et al.* (1998) found a male to female sex ratio of 1 : 1.04 in the markets of Toumodi, Côte d'Ivoire ($n = 1721$) and 1 : 1.11 in Kumasi, Ghana ($n = 858$). The ratio of adult to young was 1 : 2.86 and 1 : 1.75, respectively. The maximum birth rate was 1.8 young/year/reproductive ♀; 81–93% of the adult ♀♀ were pregnant. These high figures may have been due to hunting pressure. Maxwell's Duikers can live for more than ten years in captivity (Aeschlimann 1963, Ralls 1973).

Predators, Parasites and Diseases Common predators are African Rock Pythons *Python sebae*, Crowned Eagles *Stephanoaetus coronatus*, Leopards *Panthera pardus* and African Golden Cats *Profelis aurata*. Helminths recorded include nematodes (genera *Ostertagia*, *Bunostromum*, *Setaria*, *Skrjabinodera*, *Trichuris*) and cestodes (*Avitinella*) (Round 1968, Kamara 1975). In a study of the ticks associated with wild mammals in Ghana, Ntiemoa-Baidu *et al.* (2005) recorded the following species from duikers in Ghana: *Haemaphysalis parvata*, *H. leachi*, *Ixodes aulacodi*, *I. cumulatimpunctatus*, *I. moreli*, *I. muniensis*, *Rhipicephalus senegalensis*, *R. simpsoni* and *R. ziemanni*. Maxwell's Duiker has not been identified as an important vector for diseases of domestic animals and humans although it is doubtless susceptible to all major ungulate diseases.

Conservation IUCN Category: Least Concern. CITES: Not listed.
